To Sofia, my sweet old cat that lives so well without overthinking.

Preface

This thesis is submitted in partial fulfillment of the requirements for the degree of *Philosophiae Doctor* at Sorbonne Université. The research presented here was conducted at the Institut Pasteur, under the supervision of Dr. Rayan Chikhi and Dr. Yoann Dufresne. This work was supported by the European Union's Horizon 2020 research and innovation program under the Marie Skłodowska-Curie grant agreement No 956 229 (+Panagaia +Pasteur + INCEPTION).

The thesis is a collection of the different projects I worked on during my stay at Institut Pasteur. I begin with a small foreword of the research output of my PhD, and a gentle introduction of the scientific concepts needed to understand the rest of the manuscript. In the first section I present the published paper I am first author of, together with other unpublished work I lead or independently developed. In the second section I present other results of my scientific production, with novel elaboration of the work that appeared in the other papers I am co-author and presentation of projects that have or will be submitted to revision. The common theme is pangenomics and computational methods used to generate and use such models to infer relevant information. This essay ends with a chapter showcasing future perspectives and conclusions.

Acknowledgements

Thanks for spending time reading this.

Chapter 1

Introduction

A fundamental grasp of the data that is produced by sequencing biological organisms is essential to comprehend the research outlined in this manuscript. If already familiar with DNA sequences, how they are obtained and how they differ between species or individuals, you may proceed to section 1.3 *From reads to k-mers*.

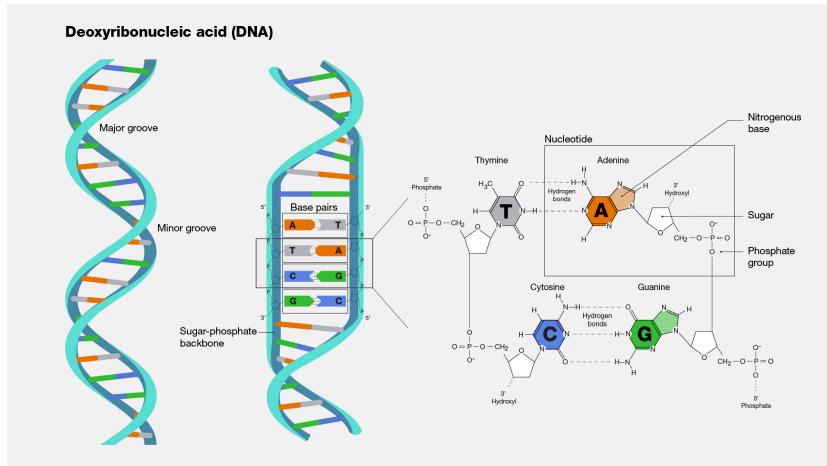

1.1 DNA, genome variation and sequencing data

DNA (Deoxyribonucleic Acid) is a complex molecule with a double helix structure that carries the genetic information of an organism. Although its discovery was the result of work by many scientists over nearly 90 years, the currently accepted model was first correctly described by James Watson and Francis Crick in 1953 at Cambridge, UK.

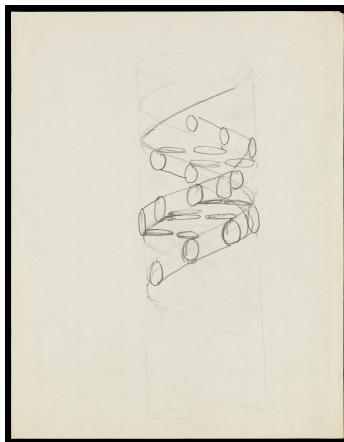

The information DNA carries provides instructions for an organism to develop, survive in the external world, and reproduce. These instructions are encoded as a sequence of monomers called nucleotides. Each nucleotide is composed of a sugar, a phosphate group, and one of four nucleobases: cytosine, guanine, adenine, and thymine. The nucleotides are commonly referred to using the first letter of their nucleobases: A, C, G, and T. In RNA molecules, thymine is replaced by uracil. The nucleotides are linked together in a sugar-phosphate backbone. Hydrogen bonds between complementary nucleotides form the molecule's double-stranded structure, with A pairing with T and C pairing with G bases. This pairing is crucial for DNA replication and protein synthesis. Figure 1.1 shows the structure of the DNA molecule and the nucleotides, with the initial drawing by Francis Crick in 1953.

To fit inside the cell nucleus, DNA is organized in very tight structures. First is coiled around proteins called histones to from a compact structure called chromatin that form loops and is kept in place by other molecules to structure a chromosome. Chromosomes are inherited by the offspring through sexual or asexual reproduction. Humans are diploids, i.e. contain 2 copies of the same chromosome, that receive one copy from the mother (the egg) and one from the father (the sperm). Both the egg and the sperm (the gametes) contain 1 copy of the chromosomes. While mammals are often diploids, other organism can be haploid (one single copy of the chromosome) or polyploid, i.e. have more than 2 copies. For example, the sugar cane plant, the world's most harvested crop by tonnage, can have more than 8 copies of a chromosome, up to 12 [2]. In humans, each nucleus of non-reproductive cells contains 23 chromosome pairs. 22 are the autosomes, i.e. the chromosomes we all have and that are not associated with sex, while the last pair is the sex one that contains 2 copies of chromosome X

1. Introduction

(a) The DNA molecule and the structure of the nucleotides, the basic piece of information of the DNA. Figure from NIH glossary [1].

(b) The DNA molecule model draw by Francis Crick in 1953.

for women or 1 X and 1 Y for men. The final part of the chromosome is called telomere while the central one is called centromere and both are regions known to contain a lot of repetitive regions that are very difficult to reconstruct from sequencing.

Finally, there is also the mitochondrial genome, that is not in the nucleus, has circular structure and is mostly inherited maternally.

1.1.1 DNA sequencing

In many biological disciplines, studying an organism's genetic information contained in its DNA is crucial. Over the years, researchers have developed various methods and techniques to extract this information from the cell nucleus: these take collectively the name of genome sequencing. Sequencing can be thought as the way we observe genomes, i.e. by sequencing fragments of DNA and assembling them computationally[3]. These processes typically involve three main steps. Here I describe them, with many simplifications, to give a brief overview:

Library preparation The first step requires hours long, nontrivial biological manipulation of samples to extract DNA from cell nucleus and purify it without causing damage. This process isolates the genetic material from other cellular components, like RNA and proteins. The DNA molecule are fragmented into pieces of different length followed by 5' and 3' adapter ligation. Some technologies require PCR amplification of fragments, while others don't.

Sequencing Next, specialized machines detect the sequence of nucleotides that compose the extracted DNA pieces. These techniques, called sequencing, use various, most of the time proprietary, technologies to determine the precise order of nucleotides (A, C, G, and T) in a DNA molecule. The raw data output of these machines are sequences of characters that are referred to as sequencing reads or simply reads.

Analysis In this step usually quality control (QC) is performed to remove adapters and too short or low quality reads. Usually the first step after QC is to assemble the sequences together or to provide them as input to a workflow specific for the required application.

The landscape of DNA sequencing has evolved significantly since its inception. In 1977, Frederick Sanger and his colleagues introduced the first widely adopted sequencing method, known as chain termination sequencing or Sanger sequencing[4]. This technique allowed to read the sequence of nucleotides in a DNA molecule for the first time in a reliable and reproducible manner. This was the technique that led to the first sequencing of the mitochondrial DNA and the first ,almost, complete human genome in 2001 [5, 6]. Sanger technology through a gel produced the first reference genomes for important organisms. While Sanger sequencing has revolutionized genetic research, it has largely been replaced by more advanced technologies. These newer methods fall into two main categories: Next Generation Sequencing (NGS) and Third Generation Sequencing. These technologies provide significant improvements in terms of speed, cost-effectiveness and data output compared to Sanger sequencing.

1.1.1.1 Next Generation Sequencing

(NGS) derives its name by launching a so-called next generation by revolutionizing sequencing with massive parallelization. This technology has continuously improved since 2005 to yield up to 8 Terabases per single sequencing run, taking it maximum 2 days and dropping the price of, for example, a single individual sequenced per almost 100 dollars [7]. The advancement consists mainly in running many reactions and analysis in parallel to produce millions to billions of reads of a length that varies between 150 and 300 bases. For this reason they take the name of short reads. While a big advantage of this sequencing method is the low error rates, with at least 80% of the bases with less than 1 error in 1000 (i.e. 99.9% accuracy). This technology is mostly dominated by a California biotechnology company called Illumina

The sequence length is the main drawback of this method. As they are too short to assemble into a high-quality *de-novo* complete genome, they are used for *re-sequencing*, i.e. to be mapped to a reference genome to infer variations from it, to be used, for example, in population variation studies. Additionally, the short length of the fragment makes sequences coming from parts of the genome not in a reference or from complex and/or repetitive regions often impossible to be mapped, loosing all the information associated to them. This problem has been partially addressed by the introduction of pair-end sequences, a technology that is now integrated in all Next Generation machines, that sequences both ends of a single DNA fragment and then associate the two reads that come from it, in order to provide more long-range information. Although this method is still not enough to solve complex variations, it is very useful to track some of the reads that would be instead be discarded and finds relevant applications in other fields, like metagenomics. In fact, I used this property of paired-end reads in one method I developed before the PhD to improve the estimation of different species inside environmental samples sequenced with NGS [8].

Finally, this technology enabled also other kind of sequencing, like STARR-seq, ATAC-seq, ChIP-seq, RNA-seq and others, that enabled to assay regulatory activity in the genome.

1.1.1.2 Third Generation Sequencing

(TGS) is the newest technology that uses alternative approaches to NGS, to solve the issues that it currently face due to the short length of the sequences. The main difference relies on the fact that while NGS uses PCR to amplify the small fragments in which DNA is broken into prior to sequencing, these new technologies directly sequence the nucleic acids in their native form. For this reason they are called single molecule technologies.

Here I will describe the two most important technologies, provided by the two companies that lead this market: a California biotech company called Pacific Biosciences, usually called PacBio, and a Uk based one, called Oxford Nanopore Technologies, or ONT.

PacBio offers "HiFi sequencing" that produces reads long up to 25 thousands

bases in length with accuracy comparable to NGS ones. This is achieved by first creating a circularized DNA from high-quality double stranded DNA and then using a DNA polymerase enzyme to read multiple times the same molecule to produce a final consensus sequence with accuracy of around 99.9%. These are long and accurate reads that enable ultra-fast assembly of human genomes [9] at a cost around \$1000 per sequencing reagents kit for a 30X coverage of a human genome.

Oxford Nanopore machines instead provide ultra-long sequences, that are on average longer than the PacBio HiFi ones and can reach up to the megabase scale (i.e. 100 times longer). The sequencing is done by passing a single-strand DNA molecule through a tiny nanopore. Each pore is associated to an electrode and a sensor that measure the current that is passing through the pore. As the DNA goes through the pore, the current changes and, thanks to a basecalling algorithm, it is possible to detect the nucleotides by the change in the current. This process is done in parallel across 800-1500 pores.

It is finally important to stress that these two technologies allow the detection of all kind of variations, i.e. small variations as well as large ones and also solve large repetitive regions as they span across thousands of bases. Moreover, both these methods allow the direct detection of DNA methylation. This is a chemical mechanism on top of the DNA molecule that regulates gene expression by recruiting proteins involved in gene repression or by inhibiting the binding of transcription factor(s) to DNA [10].

Figure 1.2 shows basic schematics of how these two technologies work.

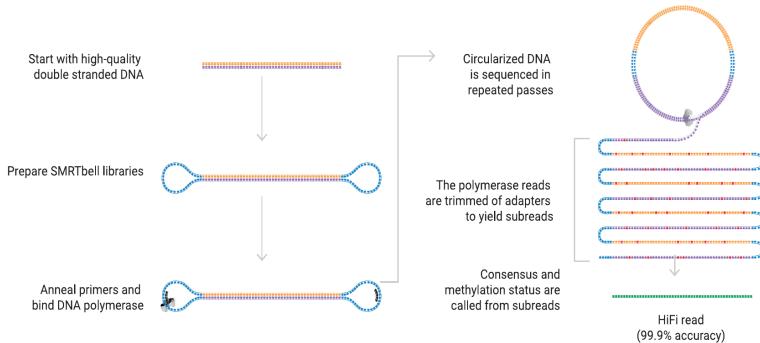

1.2 From reads to k -mers

The sequences produced by any of the aforementioned technologies are considered as text strings, i.e. successions of characters, like the phrases of this manuscript, in which each character correspond to a nucleotide. These sequences can therefore be stored in plain text formats, like FASTQ, that preserve basecalling quality information or in others, like FASTA, that retains only the actual sequence. In order to use less space and take advantage of redundancy in the sequencing data, these files are often compressed, using one of the many tools publicly available like `gzip` or `zstd`, by Facebook.

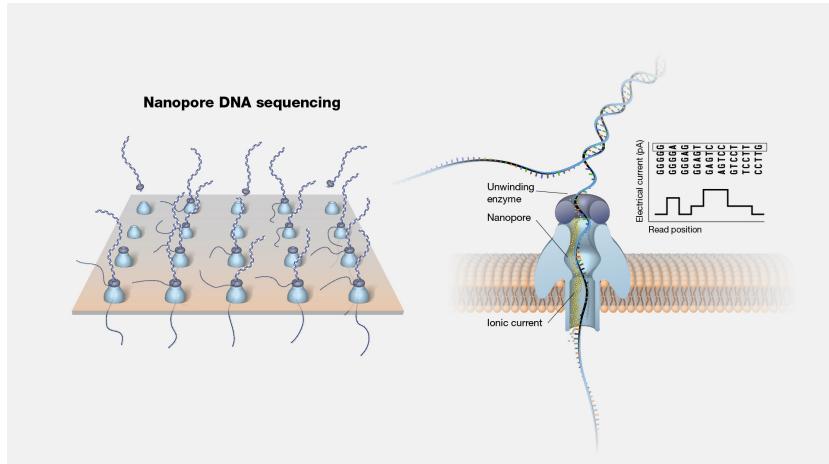

As pair-end short-reads have different features than ultra-long reads or Hi-Fi long reads, most of the tools focus on providing applications for just one single type. In cases like assembling a genome from the reads or calling the variant of the sequenced genome compared to one of reference, however, the information from different sources can be combined to provide superior results. In order to generate high-quality genome assemblies, for example, many consortia, like the Human PanGenome Reference Consortium, use Hi-Fi long reads as bases for assembly plus ultra-long reads as scaffolds to chain together the assemblies into sequences that span from telomere to telomere of a chromosome.

In the work presented in this manuscript, most of the tools will ingest as input

1. Introduction

(b) An array of pores sequences multiple molecules in parallel. A dsDNA molecule is split by the helicase enzyme and then a ssDNA sequence slowly gets through the pore for sequencing. Changes in the ionic current is used by a machine learning algorithm to infer the nucleotides of the sequence.

Figure 1.2: Third generation sequencing technologies.

or raw sequences (both NGS or TGS) or high-quality, near telomere-to-telomere assemblies. Some of the tools that I have have used and all of the ones I have developed or co-developed transform the input sequences or assemblies into k -mers to produce the desired output.

DNA alphabet The DNA alphabet Σ is composed by the 4 characters that compose the first letter of the nucleobases: A,C, G and T: $\Sigma = \{A, C, G, T\}$,

sequence a biological sequence from Σ is defined as $S = \in \Sigma^l$, with $|S| = l$, with length l that can be fixed, if originated from NGS, or variable, if

originated from TGS.

k -mer a k -mer of S is defined as $k - mer \in \sum^k$, with $|k - mer| = k$ i.e. any valid sub-string of S of length k .

As shown in table 1.1, from any sequence S , it is possible to obtain its constituent k -mers. To efficiently extract all k -mers from a sequence, the best approach is to employ a sliding window technique. This is done by identifying the first k -mer at the start of the string and then iteratively shifting the window one position at a time, appending the newly encountered character to the right while removing the leftmost character.

The length k of a k -mer is an arbitrary value, that is usually chosen depending on the kind of sequences used (cannot have $k > n$), the characteristics of the data that is used (is it from a single organism, a collection of the same species, a collection of different organisms) and on the disk or memory space that is available for computation or storage (as in table 1.1, the longer the k , the more space is used by repetitive characters). A more detailed explanation of these considerations will be provided in section XXX[QF].

As it is possible to retrieve k -mers from a single read, it is trivial to extend this property to any set of reads, for example produced by a single sequencing run of a sample. This means that a set of k -mers is equivalent to the set of reads it is obtained from. In order to characterize this transformation as lossless, i.e. without any loss of information, an association from each k -mer to the read(s) it comes from would be needed. In most of the cases this is not useful and k -mers are obtained from reads without remembering from which reads do they come from. In other, specific, applications it might instead be needed to know in which reads there are certain k -mers. More considerations on this are going to be presented in section XXX[BackToSequences].

As presented in section 1.1 the DNA is double-stranded, with A bases are paired with T ones, while C bases are paired with G ones, also called complements. If a k -mer appears in a sequence, in the other strand of the molecule there would be what is called its reverse complement. This is the spelling of the k -mer from the end to the beginning, substituting each base with its complement. For example if in one strand there appear the sequence *ACGT*, on the other strand it would spell *TGCA*.

When enumerating k -mers from a sequence or when storing them, only "canonical" k -mers are kept: this means that for each k -mer produced from a sequence, its reverse-complement is computed and only the one that is considered smaller by a certain property is kept. For example, if the lexicographic order is used, the k -mer (with $k = 4$) *ACGT* is lexicographically smaller than *TGCA* so when either of the two is seen, only the first is kept.

A classic operation that is done when enumerating k -mers from sequences is to keep track of how many times each canonical k -mer appears in the set of sequences. This is called k -mer counting and finds important applications in many genomic disciplines like metagenomics or transcriptomics.

k -mers are being used in lots of applications based on NGS short reads while

1. Introduction

they are less implied on methods for error-prone long reads because using k -mers on one side destroys the long range information provided by reads that span thousands of bases, on the other error-rates higher than NGS would produce too many erroneous k -mers that would be very difficult to correct if not with very deep sequencing, providing additional cost bottlenecks. With Hi-Fi reads and improved quality of nanopore basecalling, it is possible to overcome the error limitation and use k -mers for long reads. One example that uses advanced concepts based on k -mers is the tool **mdbq** that drastically improved assembly of Hi-Fi reads.

In the table below, reverse complements are between parenthesis and the canonical between the two (by lexicographic order) is underlined.

1.3 Genetic diversity: focus on humans.

The Human genome contains more than 3 billions base pairs and contains probably more than 20 thousands protein coding genes, i.e. specific parts of the DNA that serve as blueprint for proteins. The rest is non-coding, i.e. is not a gene but can serve as regulatory element, like enhancers, promoters and silencers or as other conserved, functional element. Differences in specific regions cause phenotypic changes that can increase, decrease or not affect the fitness of an individual.

Genetic diversity is the variability that exists between organisms at the genetic level, i.e. differences in the information enclosed in their DNA. It is the raw material for biological evolution as, without heritable genetic differences between us, we would not be able to biologically evolve. Here what I will present is valid for humans, as the large part of my work has been with human DNA sequences. Most genetic changes have no effect at all on the individuals carrying them but some can result in phenotypic differences.

1.3.1 Causes and drivers of genetic diversity in humans

There are two main mechanisms of genetic diversity: the arise of new mutations and the reshuffling of already present genetic material through recombinations and duplications. Mutations are produced by physical or chemical damage, for example caused by UV radiation, prior cell division or by errors in the DNA replications during cell division. When this occurs in germinal cells they are transmitted to the offspring, while when happening in a somatic cell (not reproductive), the mutation is not transmitted but can instead be responsible for certain type of cancer. In humans, it is estimated that a newborn carries on average 70 point mutations (one nucleotide substitute with another), 15 from the mother and 55 from the father. The amount of mutations is proportional with the age of the person and, more than induced by replication, it is due to not corrected damage.

On top of the mutations, chunks of chromosomes from the mother and the father chromosomes are shuffled to produce new combinations. The effect of this random process produces the differences between siblings with the same biological parents. Recombination is heterogeneous in the DNA and depends on some motifs that promote higher recombination. Finally, recombination is also influenced by the age, mostly of the mother, as older mothers tend to produce offspring with more misplaced recombinations, also causing the well known trisomy 21.

Without diverging too deep into population genetics, it is also important to understand how new variations are conserved, lost or fixed (become prevalent) in a population. These outcomes are driven by two main factors: genetic drift and natural selection.

Genetic drift is a process, given by the randomness in the individuals that reproduce in a specific population. This can contribute to the loss or fixation

of some variants just because of randomness and not because they provide an advantage to the individual. Specifically, in populations with small number of reproductive individuals, this can fixate detrimental variants, while in large populations, the large number of individuals buffers the event.

Natural selection, on the other hand, is a mechanism that explains human evolution: as genetic variations causes the gain or loss of specific phenotypic traits, these traits can confer positive or negative advantage compared to the rest of the individual in a population (fitness). This phenomenon can contribute selecting certain variations in a population by either contribute to the fixation or the loss of a variant. This mechanism explains our species adaptation to nutritional resources, climate and pathogens: in 10 thousand years a mutation in a gene that conferred the ability to digest milk has almost got fixed in humans, selection on certain genes explains better adaptations to cold or high altitudes and selection in HbS or DARC alleles has helped humans adapt and survive malaria infections[11].

1.3.2 Human Genomic variation: types of variants

There are various types of genomic variants: from the shortest, the single-nucleotide variants (SNV) or Single Nucleotide Polymorphism (SNP) when it is present in at least 1% of the population, is the difference of one nucleobase between two individuals. In a specific part of the genome one person can have instead of a cytosine (C) a thymine (T), like for the SNP located 14 thousands bases upstream of the lactase gene that enables the lactase persistence mentioned earlier[12]. A second group of small variants is made of insertions and deletions (called together *indels*): these are events in which it is present or missing a group of less than 50 nucleotides. The number of nucleotides is an arbitrary threshold used to better separate them from other kind of variations. Specific types of indels are the tandem repeats that, as the names suggests, are insertions or deletions of small repeated sequences of DNA. These repetitions usually are one after the other with no other sequence in between [13].

These groups of small variants, shown in figure1.3 are the most described, studied and associated with diseases as they were the only one consistently detectable with NGS sequencing. For these reason, studies that tried to associate genomic variation with diseases commonly used only these kind of variants.

The other kind of variations are the ones that stretch at least 50 nucleobases and that can reach the dimension of large chunks of the chromosomes: they are called structural variations (SVs). These can be indels or tandem repeats with the repeated section longer than 50 nucleotides, accounting for nearly half of all SVs, that take the name of Copy Number Variants (CNVs). Moreover, there are also inversions, in which a chunk of DNA is inverted compared to another and translocations in which pieces of two different chromosomes trade places [13].

Finally, it is important to remember that these kind of variations can be on just one haplotype (copy of the chromosome) or on both: this distinguish between heterozygous and homozygous alleles.

1. Introduction

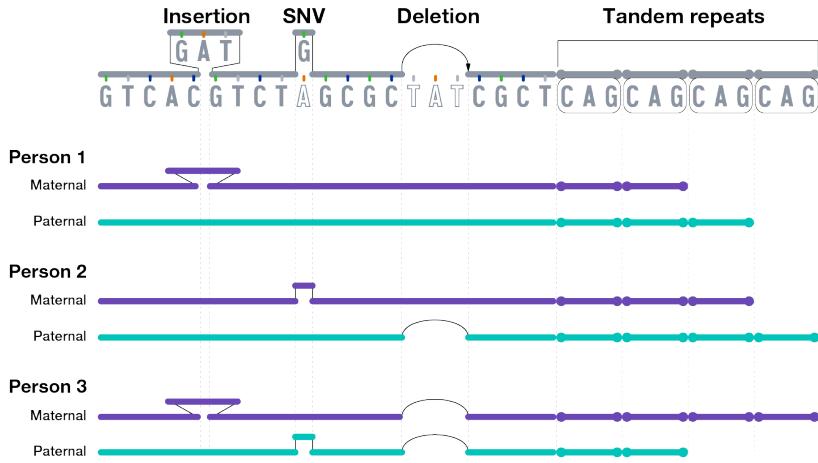

Figure 1.3: Graphic showing the types of small genomic variants [13]

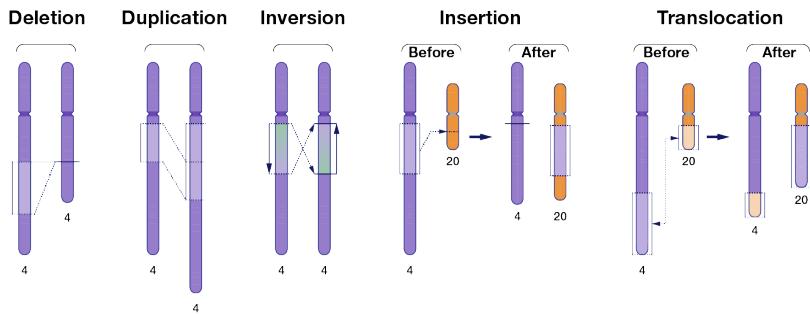

Figure 1.4: Graphic showing the types of large genomic variants [13]

1.3.3 The importance of studying genomic diversity in populations context

DNA differs between individuals of the same population (inter-individual) and between different populations of the same species (inter-population): figure 1.5 shows the percentage of inter-individual variation for four close primates. Different species can differ in the amount of genetic variation that is s As

discussed before, differences in DNA are given by having a different nucleotide at the same place (SNV), indels and large and complex variations, up to Megabases, that can produce different counts of copies or different ordering of a same region. On average, each human carries around 10 thousands amino-acid altering mutations, 300-400 gene disruption events (like stop, splice and indels) affecting 200-300 genes and is heterozygous at 50-100 mutations associated with an inherited disorder [11]. Finally, even when close species share a large portion of genetic material, structural changes that rearrange the same material in different order or invert it, contribute to meaningful changes. In figure 1.6 it is shown how the chromosome 7 and 16 of some primates, even if very similar, differs in terms of organization. These large structure rearrangements are thus fundamental to understand the biology of organisms. It is This is because the variation in DNA is produced by two main mechanisms: mutations and recombination.

Moreover, genetic diversity is driven by two main factors: genetic drift and natural selection. Genomic duplication followed by adaptive mutation is considered one of the primary forces for evolution of new functions.

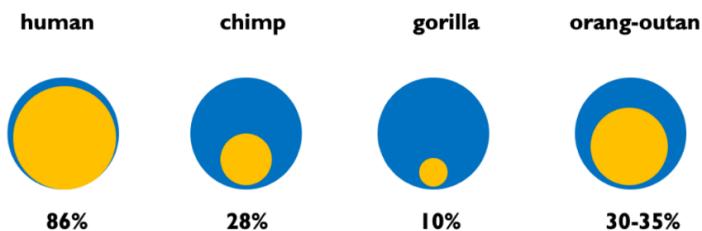

Figure 1.5: Share of inter-individual (yellow) and inter-population (blue) diversity for four different primates. While for humans the majority of the diversity is within populations, for other primates it is between populations. This shows how Humans are more mixed than other primates. Percentage shows the inter-individual variation share [11].

1.4 Pangenomics, pangenomes and pangenome graphs

1.4.1 The premises for Pangenomics

There are a number of factors that must be taken into consideration to understand one one side the need for a new paradigm and on the other side the conditions that lead to its development. Here I will briefly expose some of them before diving into pangenomics approaches and methods.

1.4.1.1 A single linear genome for all analyses

Since the first complete genome sequences have been available in the late '90, all analysis based on sequencing data depended upon the use of a single linear

1. Introduction

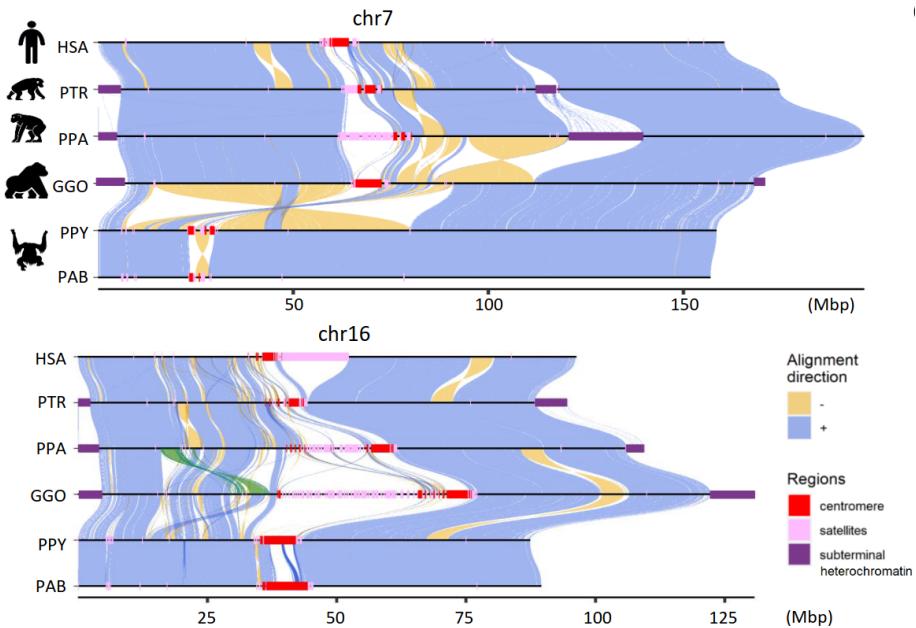

Figure 1.6: A comparative ape alignment of human (HSA) chromosomes 7 and 16 with chimpanzee (PTR), bonobo (PPA), gorilla (GGO), Bornean and Sumatran orangutans (PPY and PAB). The image on the top shows most of the chromosome 7 is conserved except for large inversions happening between the species. The image below shows complex inversions in chromosome 16. Image taken from 'Complete sequencing of ape genomes' [14].

reference genome, i.e. the best version of the genome available for any species. This reference sequence can originate from the genome of a single organism or be a patch and consensus of multiple available genomes of the same species. Its purpose is to use it to infer information from newly, less refined, genomes that are being sequenced. We now know that this approach is suboptimal in a wide range of applications as a lot of genetic material of the species cannot be present in a single linear representation: this is valid for eukaryotes and even more for bacteria, that tend to be very diverse even in the same strain. The goal would therefore be to find a representation that provides more genetic material of a single species by intelligently combining the information from genome of multiple organisms and their differences.

1.4.1.2 A quantity and quality revolution

In the last few years we are witnessing a new revolution in sequencing. As the price of sequencing is lowering more than 2x per year, from \$1/basepair to $\$10^{-7}$ /basepair[15], new scientific discoveries and technological advances are leading to a remarkable increase of quality, in term of per-base error rate, and

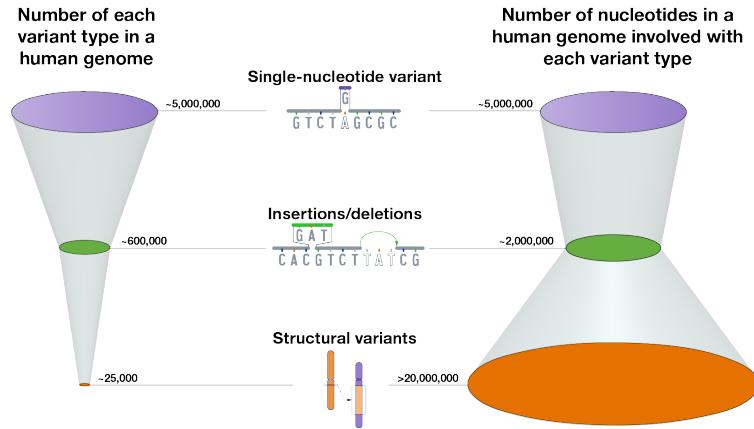

Figure 1.7: Spectrum of Human Genetic Variation. While SNPs are the most common variation event, their impact in the total amount of bases in a genome is 4 times smaller than the one of Structural Variations, that are 200 times less frequent. This shows the great need to consider SVs in genomic analysis and not to stop at the SNP/indel level.

throughput of TGS. This means that in the next future we will dispose of a rich wealth of high quality sequencing information to produce hundreds or thousands of new first grade assemblies of large eukaryotic genomes.

For example, the history of complete human genome assemblies clearly exposes how much more high quality genomes it is now possible to generate. The Human Genome Project took 13 years to produce its result [16] and the absence of long reads with low error rate made it impossible to automatically resolve repetitive regions like telomeres and centromeres [17], producing a reference only 92% complete [18]. This problem was only solved in 2022 with a new, reference genome that did not have any gaps or unresolved regions, from the telomere to the other telomere of each chromosome [18]. Now, many consortia are producing increasingly more genomes to a level comparable to the one produced in 2022. For example, the HPRC, i.e. the Human Pangenome Reference Consortium, released 47 new human genomes (92 haplotypes) in 2021 and has recently released other 153 genomes to a total of 400 haplotypes of very high quality.

Finally, it is important to understand the quantity of biological information produced. As shown in table 1.3, the number of base pairs sequenced has more than doubled each year since 1995. As this is faster than the famous Moore's law on computing power, it is becoming evident that a new paradigm is needed to store and analyze such wealth of data. Public repositories, like Sequence Read Archive (SRA) and European Nucleotide Archive (ENA), are rapidly increasing the number of samples being sequenced and rendered publicly available to

1. Introduction

everyone, with tens of billions of millions of basepairs from genomic samples, as shown in figure 1.8. Other repositories of genomic data with associated medical metadata, like the UK biobank that comprises around 500 thousands individuals, are also emerging. These conditions are pushing the adoption of novel methods to process and analyze genomes.

year	genome(s)	base pairs
1995	Bacterium	$2 * 10^6$
2001	Mammal	$3 * 10^9$
2013	2500 humans	$7.5 * 10^{12}$
2021	1M genomes	$3 * 10^{15}$

Table 1.3: Base pairs had a 10^9 increase in less than 30 years. As $10^9 \cdot 2^{30}$ (from $\log_2(10^9) = 29.9$), the base pairs have more than doubled each year[15].

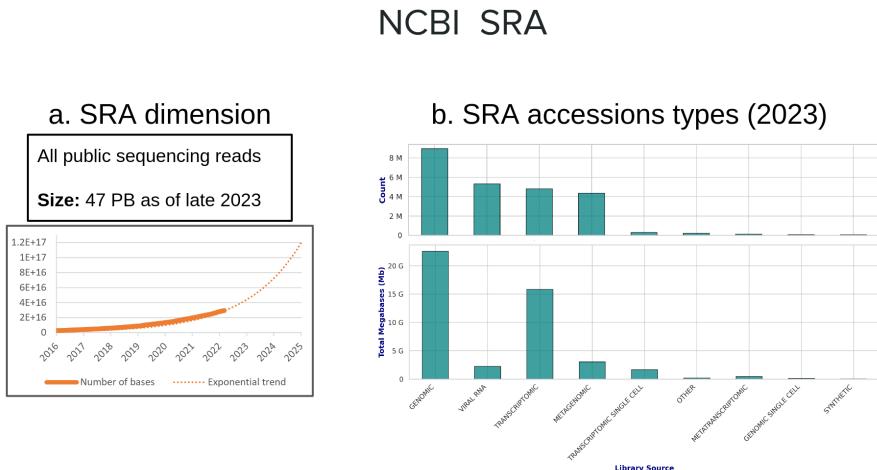

Figure 1.8: a) The size in PetaBases ($\text{peta} = 10^{15}$) of the SRA archive; b) The type of data in the SRA database shows the vast amount of genomic data available. Image made from Rayan Chikhi's slides.

1.4.1.3 The need to better understand difference between genomes

The ability to produce such good data is the main enabler of increasing efforts from the scientific community to propose new methods to analyze genomes: not anymore by comparing new genomes against a single good reference sequence but by comparing it in a comprehensive representation of the species.

Moreover, as new high quality sequences and assembled genomes are available, complex and/or highly repetitive regions can be now represented also for new

genomes therefore enabling comparison between the ones of different genomes. This is very important as up until these improvement in sequencing and assemblies arrived, analyses were mostly blind to large, complex and/or repetitive structural variations. As we now know that these are the ones responsible for most of the difference between human genomes, new proposed approaches should provide new and better tools to understand, represent and analyze such variations. Finally, as a single reference sequence cannot enclose all the possible structural variations of a population into a linear model, the need for a change in data structure for genomics arises.

1.4.2 Pangenomics

Pangenomics is therefore a rapidly evolving field in genomics that aims to capture and analyze the full genetic diversity within a species or a group of closely related species. It does not rely on a single, linear reference genome, but on comparing any genome with a group of other similar ones, as it seeks to represent all genetic variations and structural differences across collection of genomes. It leverages the availability of large collections of high quality assemblies of many species to overcome the observational bias of using a single haplotype as reference for a whole population. As shown in figure 1.9, the pangenome model aims at representing all variations among a group of complete genomes by describing the direct relationships between them, while in the linear model each genome is compared only to the reference: while in standard genomics genomes are compared between each other via indirect difference to the linear reference, in pangenomics the comparison is direct. When a new genome is added to a collection, in genomics it compares just to the reference while in pangenomics it does with all the genomes present in the model. It was first conceptualized for bacterial genomes, and at gene level, without considering non coding regions. This was mostly due to the fact that bacteria share genes between each other, generating high diversity in the gene repertoire between organisms of the same species or strain. The first proposed pangenome model had a subdivision between a core genome, made by genes present in all individuals of a species, and a dispensable or accessory genome, with genes present in some, but not all, individuals.

This definition would then extend to a more general model that would consider variations at the nucleotide level to contain all variations in a set of genomes.

1.4.2.1 Pangenomes

A pangenome can be therefore be considered any collection of genomic sequences to be analyzed jointly or to be used as reference. This definition provides two important concepts for the rest of the studies provided in this manuscript:

Model the pangenome is not a well-defined structure or model but can be from a simple collection of sequences to complex data structures. This means that

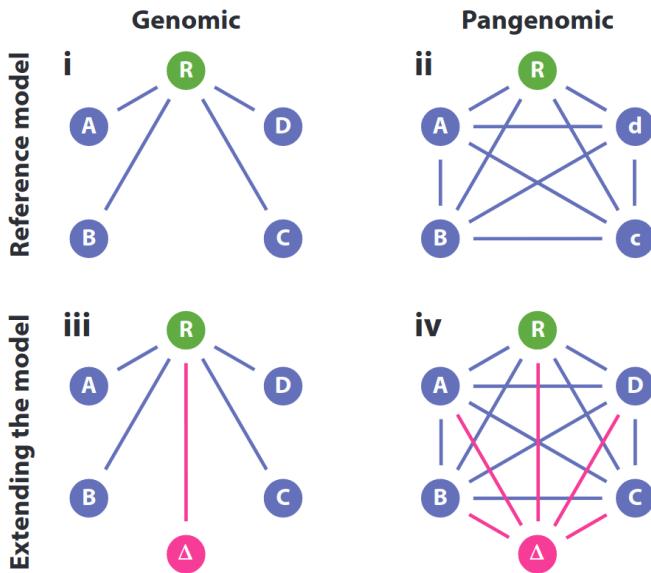

Figure 1.9: The genomic vs pangenomic model i) In the genomic model each genome is compared only to the reference sequence. Any comparison between a pair of genomes is done indirectly via their difference with the reference. ii) In the pangenomics, variations are described in a relative way for any genome. Any pair of genomes can be compared directly. iii) In the genomic model, to add a new genome in the collection it has to be compared to the reference. iv) In pangenomics, each new genomes added to the model is automatically compared to all the ones in the collection. Figure from [19]

different approaches are developed and used depending on the application of interest;

scope a pangenome can be either used as:

- a new reference for a specific species to be used for analyses in a similar way as linear genome. This means that a large consortium would be producing a representation that is accepted as new standard. For the Human genome this is done by the HPRC consortium as the T2T consortium produced the best-quality linear reference genome [18].
- a different model that can be used to study a set of genomes, without needing *a priori* to use a reference. This model can find applications in population variation studies.

Pangenomes can be an unaligned set of sequences. This is the most basic case, with no processing of the data but that conserve the full information from

the assembly without introducing any bias or error. In this sense, a group of complete genomes of a family, species or genera can be considered a basic form of pangenome. They can be used together to infer direct relationships between each other, via alignment. For example, as the T2T consortium has fully resolved the centromeres of 2 human genomes, when considered together, it is possible to detect small-scale and large-scale centromere variations, something that was never possible before [20]. By having high quality assemblies of various apes, it is possible to reconstruct complex and large variations and rearrangements in chromosomes between them and the human genome that could not be detected before [21].

A multiple sequence alignment (MSA) of haplotype-resolved complete genomes can be considered a pangenome. This data structure originated from complex and costly alignment operations is the basis of many computational approaches, also in pangenomics, like the founder graphs. These models are limited in scope as it is impractical as it does not work well when genomes are too large, have complex variations or are very divergent.

Pangenomes can be also represented as sets of k -mers. This approach has several advantages: it scales very well to large collections of genomes, accepts as input from raw reads to complete assemblies and is unbiased. The drawbacks mostly consist on the right choice of the k -mer length and the

1.4.2.2 Pangenome Graphs

Graphs are a natural way of directly representing information between a group of objects that share some properties: they provide a human interface to a set of relationships.

A graph is a mathematical structure used to represent associations between abstract entities. It consists of two main components:

Nodes are the entities of the graph that possess some properties (like a **(vertices)** value or label);

Edges are the connections between the nodes that represent the interactions between the nodes (shared property or difference).

Graphs are widely used in a lot of applications, mainly to describe and interpret complex structures in social, transportation or computer networks.

Graphical models are largely adopted to represent pangenomes. They differ in the property associated to the vertices and therefore in the information provided by the edges.

De Bruijn have nodes with labels representing k -mers and overlap relationship **graph** between k -mers is expressed using edges; k -mers and their reverse complement are represented by the same node, so the graph is bidirected, with edges connecting a strand of a node label to another strand of a node label.

1. Introduction

Directed genome have nodes labels representing a sequence and edges signal adjacency graph of two sequences in at least one genome. A sequence and its reverse complement are assigned to two different nodes, as the only information represented by the graph is the contiguity of pairs of sequences.

Bidirected genome have nodes with a label and two sides, i.e. the start and the end of graph the label. Edges connect one side of a label to the side of another, to provide the starting point of the sequence spelled. If a node is traversed from left to right, it is the forward strand of the sequence, if done right to left, it is the reverse strand of the DNA [22].

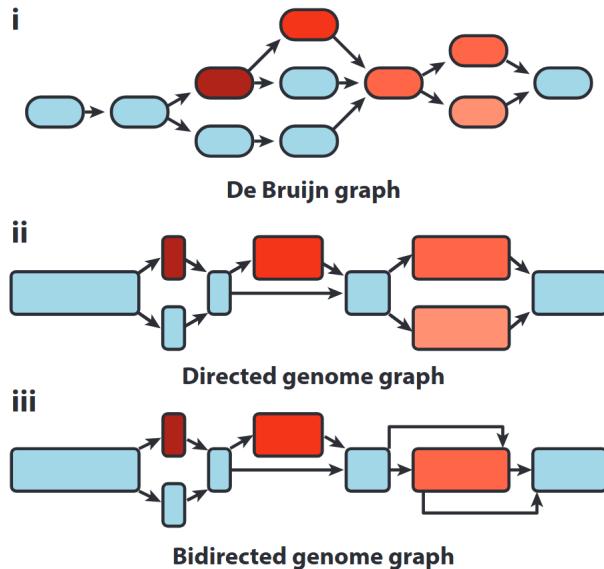

Figure 1.10: The three main kind of graphs used to represent pangenomes. Figure from [19]

The choice of a particular model relies mostly on which is the envisioned application: there is no one-fits-all solution because of trade-offs between optimal desiderata. A model that enables useful visualization can be not suited for large collections of genomes, other that allow the addition of new genomes without recomputing everything from scratch, also called dynamical-updates, are not the best for efficient compression and storage and so on.

Genomic variations in graphs consist of bubbles representing alternative paths between a source node and an end node. Different variations produce different kind of bubbles and different models produce bubbles with different patterns. Two examples for DBG and genome graph can be seen in figure 1.11 1.13

Below I present the two main models actually used for pangenome graphs construction: Variation graphs and De Bruijn graphs.

1.4.3 Variation Graphs

Variation graph are an enhancement of bidirected genome graphs with paths. Paths correspond to walks in the graph that visit nodes in an assigned orientation to reproduce sequences provided as input, as shown in figure 1.11. It therefore consists of a bidirected genome graph constructed from the sequences in the input genomes plus a list of paths that spell such sequences inside the graph. This data structure has been first proposed to represent textual variations.

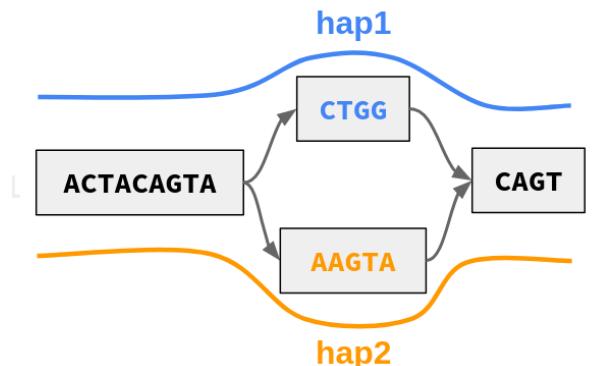

Figure 1.11: An example of variation graph, in which haplotype1 spells the sequence *ACTACAGTACTGGCAGT*, while haplotype 2 spells the sequence *ACTACAGTAAAGTACAGT* [3].

As shown in figure 1.12, the variation graphs represent the conservation and variation in a system: it is therefore a very good model to represent the direct relationships between a group of genomes. Variation graphs of genomes can now be constructed thanks to the advent of TGS and complete high quality assembly pipelines. As already discussed, genomes are full of repeats, making assembly is hard, especially if the only information available is reads shorter than the repeat sequences, as with NGS.

Variation graphs can be generated in a direct, all-v-all unbiased way or in a iterative, reference driven manner. The pros of using a variation graph are:

- variation is intuitive when visualizing the graph

1.4.4 De Bruijn Graphs

As variation graphs, dBGs are not born with pangenomics. They are a well-known data structure that found great application in genome assembly, especially with NGS. A dBG is a data structure that represent a collection of input sequences as a set of k -mers. It therefore reduces the redundancy in the data by storing only once each unique k -mer seen in the input. The graph has as node labels the k -mers and directed edges between nodes indicate $k-1$ overlap between the two k -mers. dBGs are also bidirected, as each k -mer encodes also its reverse

1. Introduction

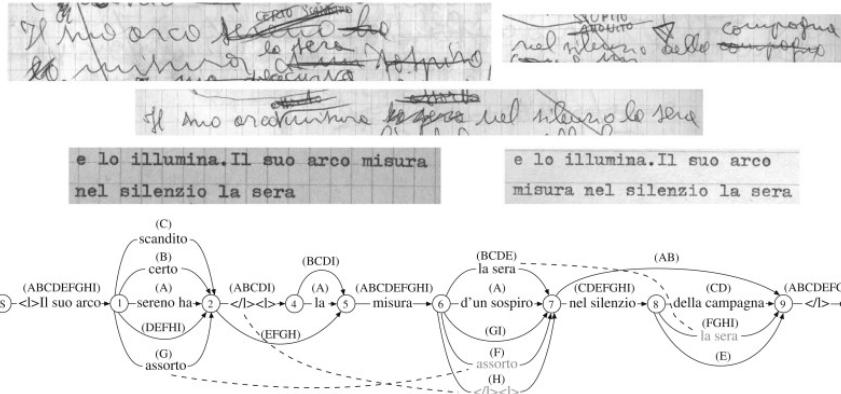

Figure 1.12: Instead of having to perform all the pairwise comparisons of the nine versions of Valerio Magrelli's "Campagna Romana" poem from 1981, the variation graph structure describes the differences between them. It also removes the high redundancy in the versions of the poem [23, 3].

complement: the one present in the label of the node is usually the canonical one. Bidirected edges encode the strandness of the k -mer of the starting node as well as the one of the ending node. The choice of k depends on multiple factors

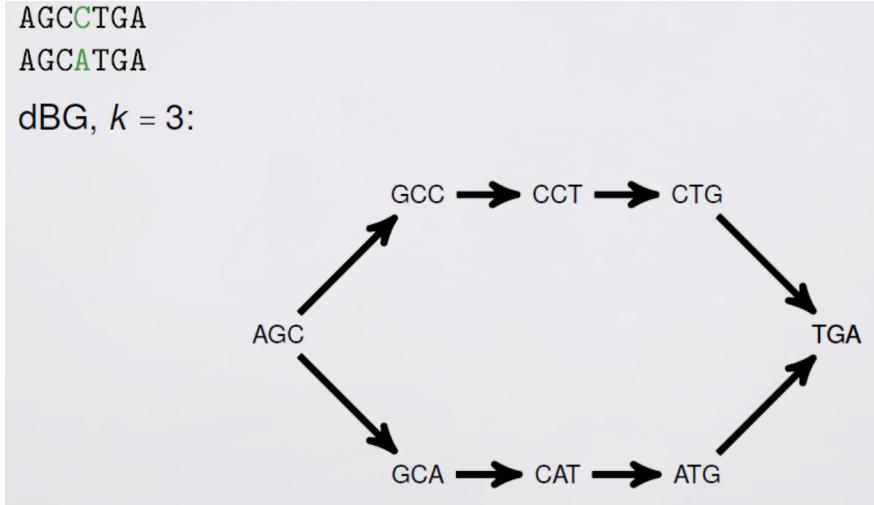

Figure 1.13: Example of dBG for $k = 3$ with a bubble representing a SNP.

and in fact is a trade-off between:

Specificity The larger the k , the sparser is the set of k -mers of the dBG in the space.
While smaller k (21-31) is more general and fits most solutions, larger k

(61-100) provides more specificity. This is because 2 or more genomes are have greater probability of sharing small subsequences than large ones.

variation resolution While variation is always encoded in a dBG, larger k values produce a sparser graph, in which there are less nodes with label k -mers that are repeated multiple times in the genome. This means that once visualizing a specific region of the graph, it is possible to detect local variations and not be confounded by other nodes and edges coming from other part of the genomes that share k -mers present in the region.

Space As shown in in table 1.1, larger value of k produces more redundancy and a greater number of basepairs with the same input sequences. If the collection to study is large, smaller k can provide beneficial features for disk storage or computational resources needed when using it.

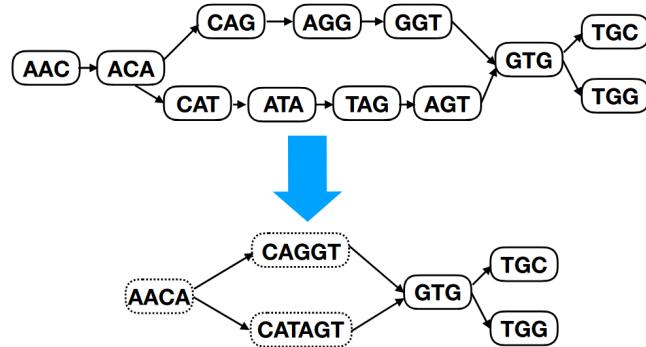

1.4.4.1 Colored and Compacted De Bruijn Graphs

In order to produce a more compact and informative representation, in pangenomics it is used a particular version of the dBG that

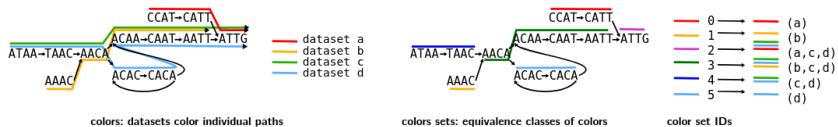

- compacts simple paths (no branching or bubbles), i.e. if there is a chain of at least two nodes that have just one entering edge and just one outgoing edge, the nodes gets compacted into a single one and the label becomes the extension of the first k -mer with the last nucleotide of the labels of the subsequent nodes. Such labels are no longer of length k and thus are not k -mers: they are called unitigs and provide a more succinct representation of the k -mers in the dBG 1.14.
- stores for each k -mer (also inside unitigs), the genome in which it has been seen: this information is called color. The color of each k -mer in the ccdBG is stored in a very compressed way in order to reduce space. Colors allow useful analysis by not only using the presence or absence of a k -mer in a dBG but also in which genomes it was observed.

While k -mer compaction into unitigs can be done at a second moment starting from a dBG, novel methods tend to compute unitigs directly, without passing for the dBG construction.

Colors can be a confusing term as it is used for two different cases: they can represent directly the dataset of origin or they can represent any combination of dataset of origin that is seen associated to a k -mer (also called color sets) [24]. The color sets is the most used model as, instead of remembering for each k -mer which are the datasets in which it is contained, it assign an integer to any combination of dataset seen and then associate it to the k -mers, in order to save space, as shown in figure 1.14.

(a) Compacting a dBG from the two sequences AACAGGTGC and AACATAGTGG into a cdBGs reduces paths of nodes with in-degree and out-degree of 1 into a single node. Figure from [25]

(b) The two kind of colors that can be used on ccdBG: colors and color sets.

Figure 1.14: Compaction and colors: the two main characteristic of a ccdBG compared to a dBG. Figure from [24]

1.5 Outline

In the work presented below, we investigate the graphical pangenome representation on the features presented in the sections above. We focused mainly on the construction of such models, their underlying data structures and the downstream application they enable.

The contributions presented in this paper are the following:

1. **An analysis of pangenome construction methods and their applications.** Even if the variation graph model has been devised around 15 years ago, its application for pangenomics is very recent. dBGs are instead a known model that has been extensively used for genome assembly and their application to pangenomics is relatively straightforward. We used all the state-of-the-art tools to produce pangenome graph based on these two representations using a large collection of complete human genomes and tested computational resources, variation representation and applications.
2. **A novel construction of pathogenic yeast strains to discover chromosomal translocations.** Pangenome graphs can be used to

investigate complex structural variations in genomes. In this case we sequenced, assembled and analyzed a group of 11 samples. We modified a variation graph construction pipeline to detect cross-chromosome events and discussed differences in the final representation.

3. **A unitig matrix construction pipeline for presence/absence or counts.** We proposed a small pipeline, based on already published tools and a novel method, **kmattool**, a pipeline to build unitig matrices with abundances from a set of genomes via k -mer matrix and to directly generate a presence absence unitig matrix using ccdBGs.
4. **A novel superkmers enumeration and sorting method based on a special representation.** We propose a novel way to encode and store superkmers that preserves locality for the ones sharing the same minimizer to improve sequence queries. We also propose a tool to enumerate and sort superkmers from a set of sequences using this model.

The next chapters present this work and discuss the possible directions for future work based on it.

Chapter 2

Pushing the limit of pan-genome construction methods

In this first chapter I present and discuss two projects in which I have pushed the current limit of pan-genome constructing methods to provide useful insight of their features, of their relative advantages and of the improved capabilities compared to current genomic approaches.

In the first one I have analyzed the current state of the art methods available at the moment and stress-tested them by also generating what was, to the best of my knowledge, the largest human pan-genome produced at the time.

The second one is the generation of a yeast pan-genome reference for the species *Lodderomyces elongisporus*, with some of the tools used in the aforementioned work, to demonstrate how pan-genomes are a superior representation to investigate cross-chromosomal rearrangements compared to the linear reference used by commonly used genomic tools. In order to best capture this large rearrangement between three chromosomes, I had to modify and customize one of the most used variation graph pangenome construction pipeline and compared to other two graphs. Here I present the challenges faced, discuss which data structure to use to achieve biological correctness, genome variation resolution, scalability or downstream application usability and show how a pan-genome enables improved analysis of inter-chromosome rearrangements.

2.1 Motivation

The paper that follows this section originates from a discussion early in my PhD journey on which were the best tools suited for large cohort pan-genome construction, specifically for large Eukaryote genomes, like primates. As pointed out in the introduction, there is no one-fits-all solution and most of the tools, at the time of the analysis, were freshly released or distributed under development. It was therefore important for the community of developers and users of such new tools and models to understand the limitations and the potential of the new pan-genomic methods.

In order to perform a thorough assessment of the best available methods, we tried to mimic the conditions that they could face in the near future. We therefore decided to test on the largest collection of high quality human data as it is paramount to understand how pangenomes can be used and adapted to be the platform of future large genomic studies.

As introduced in section ??, there are multiple ways of representing a group of genomes to be analyzed or used jointly. One that took traction in the last few years has been graphs. Graphs can represent the sequences as labels of nodes,

2. Pushing the limit of pan-genome construction methods

relationship between them (adjacency or overlap) as edges and infer difference in the genomes as different set of nodes in them.

We specifically focused our attention on the most used graph models: variation graphs and De Bruijn Graphs. In variation graph edges represent adjacencies, i.e the genome is spelled by a walk on nodes connected by an edge. In De Bruijn Graphs they represent overlaps, i.e. the suffix of a node is the prefix of the next node connected to it: this implies that edges can exist between nodes that are not adjacent in the genome. As discussed in the next sessions, this distinction implies several differences in how these graphs can be used for downstream analysis.

In this article, we surveyed the the methods and tools that build such graphs, then tested them on different dataset sizes and permutations, and finally analyzed the resulting representation's features. The outcome is a small guide on which are the best applications for each of these tools and an analysis of how they represent variations in genomes.

Chapter 3

Comparing methods for constructing and representing human pangenome graphs

Published in *Genome Biology*, November 2023, volume 24, issue 1, article number 274. DOI: 10.1186/s13059-023-03098-2.

Abstract

Background: As a single reference genome cannot possibly represent all the variation present across human individuals, pangenome graphs have been introduced to incorporate population diversity within a wide range of genomic analyses. Several data structures have been proposed for representing collections of genomes as pangenomes, in particular graphs.

Results: In this work we collect all publicly available high-quality human haplotypes and construct the largest human pangenome graphs to date, incorporating 52 individuals in addition to two synthetic references (CHM13 and GRCh38). We build variation graphs and de Bruijn graphs of this collection using five of the state-of-the-art tools: **Bifrost**, **mdbg**, **Minigraph**, **Minigraph-Cactus** and **pggb**. We examine differences in the way each of these tools represents variations between input sequences, both in terms of overall graph structure and representation of specific genetic loci.

Conclusion: This work sheds light on key differences between pangenome graph representations, informing end-users on how to select the most appropriate graph type for their application.

3.1 Introduction

In recent years, the majority of studies on human genetics have been conducted on the basis of comparing new samples against a single, standard reference sequence. This reference sequence is a linear succession of nucleotides that acts as a blueprint of the human genome. It is routinely used to align raw sequencing data to it in order to find variations between genomes, e.g. single-nucleotide polymorphisms (SNPs), insertions or deletions (indels). It also is the backbone of the UCSC Genome Browser [1] which enables inspection of genomic and epigenomic features. Despite updates that have improved the quality of the human reference sequence in the last two decades, its linear form severely limits the ability to capture population genetic diversity. For instance the locations of frequently observed structural variations cannot be easily integrated into a linear reference. To see this, consider the difficulty of designing a suitable coordinate system in the presence of (possibly nested) structural variants. Having a single genome as reference sequence also introduces an observational bias towards the chosen alleles that were integrated into that sequence, negatively impacting many primary analyses such as reads mapping, variant calling, genotyping and haplotype phasing. As a result our ability to precisely characterize structural variants, SNPs and small indels is limited [2, 3, 4]. The GRCh38 human reference genome is estimated to miss up to 10% of our species genetic information [5].

Improvements in sequencing data quality and length, as well as genome assembly methods, are providing a fast expanding collection of haplotype-resolved human genome assemblies. If adequately combined together, these high-quality individual genomes may offer an powerful alternative to the linear reference. There now is an active line of research on pangenomes, i.e. data structures that represent a collection of genomic sequences to be analyzed jointly or to form a reference [3, 6].

Pangenome-based approaches have been shown to improve biological analyses. Pangenomes are at the basis of bioinformatics tools that perform high-quality

short read mapping [4], genotyping of SNPs, indels and SVs [7], RNA-seq mapping [8]; de novo variant calling [2]; to store, compress and retrieve high quality genomes [9]; to condensate all the information from a high number of genomes to then visualize specific regions or perform ad-hoc analysis, particularly on complex loci, SVs and tandem repeats [8]. These results pave the way for new applications, e.g. genome-wide association studies, where more precise identification of variants can improve the scope of genetic studies in aging, human diseases, and cancer [3, 6].

Several pangenomic data structures have been proposed: multiple sequence alignments, de Bruijn graphs, cyclic and acyclic variation graphs, and haplotype-centric models that use the Burrows-Wheeler transform [3]. Each of these approaches aim to represent a collection of genomic sequences in an efficient way, to store, visualize, and retrieve differences of interest between the considered genomes. Graph-based pangenome data structures, such as the de Bruijn graph and the variation graph, appear so far to be the most advanced in their ability to handle large amounts of input data. They are capable of representing tens to hundreds of human haplotypes simultaneously. Variations graphs use a sequence graph and a list of paths to store input haplotypes, while de Bruijn graphs store all haplotype k -mers annotated by their haplotype(s) of origin. Scaling pangenome graph data structures to store hundreds of genomes is a challenge that requires significant computational resources and engineering efforts. Many software tools have been created, here we briefly describe major ones. Pantools [10] and Bifrost [11] are two methods that have been developed to generate pangenomes for analysis on large collections of genomes, mostly for applications in phylogenetics and bacterial genomics. The PanGenome Graph Builder (**pggb**) [12], **Minigraph-Cactus** and **TwoPaCo** [13] are methods for building general-purpose pangenome graphs. **Minigraph** [14] builds a particular type of pangenome graph by aligning sequences in an iterative way to a reference template. Minimizer-space de Bruijn graphs (**mdbg**) [15] are variants of de Bruijn graphs that can efficiently represent very large collections of bacterial pangenomes (e.g. 600,000 bacteria). **vg** [2] builds variation graphs from a reference sequence and a variant calling file (vcf) that contains a list of variations from it. Many human pangenomes have been generated, e.g. using Pantools [10] (7 genomes), **Minigraph** [14] (94 haplotypes), **Minigraph-Cactus** [16, 17] and **pggb** [8] (94 single chromosomes), and **TwoPaCo** [13] (100 simulated genomes). Lastly, a draft version of a human reference pangenome constructed using **pggb** and the **Minigraph-Cactus** pipeline has appeared in a very recent article from the Human Pangenome Reference Consortium [8]. These pangenomes are still limited by some factors: at the present moment, the number of high-quality haplotype assemblies is still low, even if it is expected to grow in the future; the vcf files containing variation are limited in term of bias, type of variation or number of samples; the population representation, even if opened up in recent years to more ethnicities, is still affected by sampling bias.

3. Comparing methods for constructing and representing human pangenome graphs

3.2 Results

In this article we provide a comprehensive view of whole-genome human pangenomics through the lens of five methods that each implement a different graph data structure: **Bifrost**, **mdbg**, **Minigraph**, **Minigraph-Cactus** and **pggb**. We examine several features of pangenome graphs, in particular their scalability and how they represent genetic diversity. To this end we collected all publicly available high-quality human haplotypes and attempted to construct pangomes of various complexity with each selected tool. Although **vg** has been widely used at the basis of relevant pangenome-based discoveries, for example on fast and accurate short read mapping [4], we decided to not consider it in our analysis for two main reasons: the bias introduced by the reference sequence that is used as the backbone of the graph (and associated to the vcf) together with the limited capacity of this method to integrate structural variations from many genomes. We believe both aspects are drivers of the use of pangenome graphs.

Scalability and characteristics of pangenome graph construction tools

We ran the above five tools on three datasets consisting of 2, 10, and 104 human haplotypes respectively (Table 3.3). We compared the computational performance of construction algorithms as well as characteristics of the produced pangenome graphs. The goal is to assess the ability of each method to scale to data available in the near future, i.e. thousands or even millions of human genomes [5].

The performance of each tool is evaluated in terms of running time, peak memory, disk space required by the output data structure (graph and annotations). We also compared the number of nodes, edges and connected components as indicators of the complexity of the graph. Results are displayed in Table 3.1.

In terms of running time, **mdbg** is two orders of magnitude faster than other tools on all considered datasets, taking around two minutes on the H2 dataset and half an hour on H104. **Bifrost** is the second fastest on H104 (18 hours), and **Minigraph** is the second fastest on H2 (8 minutes). **Minigraph-Cactus** takes one order of magnitude more time than **Minigraph**. We could not obtain graphs for **pggb** and **Minigraph-Cactus** on H104 as for the first execution did not finish after 2 weeks and the second returns an error.

In terms of memory usage, **mdbg** consistently uses less than half the memory of other tools (31 GB on H104), followed by **Minigraph** (61 GB on H104). On H2 all tools used between 8 and 66 GB of memory.

All tools used reasonable disk space to store the resulting graph, ≤ 12 GB for H10 and ≤ 38 GB for H104. Although **Minigraph-Cactus** and **pggb** retain all variations and are the only two tools able to reconstruct the input haplotypes directly from the graph, they are the second and third most efficient

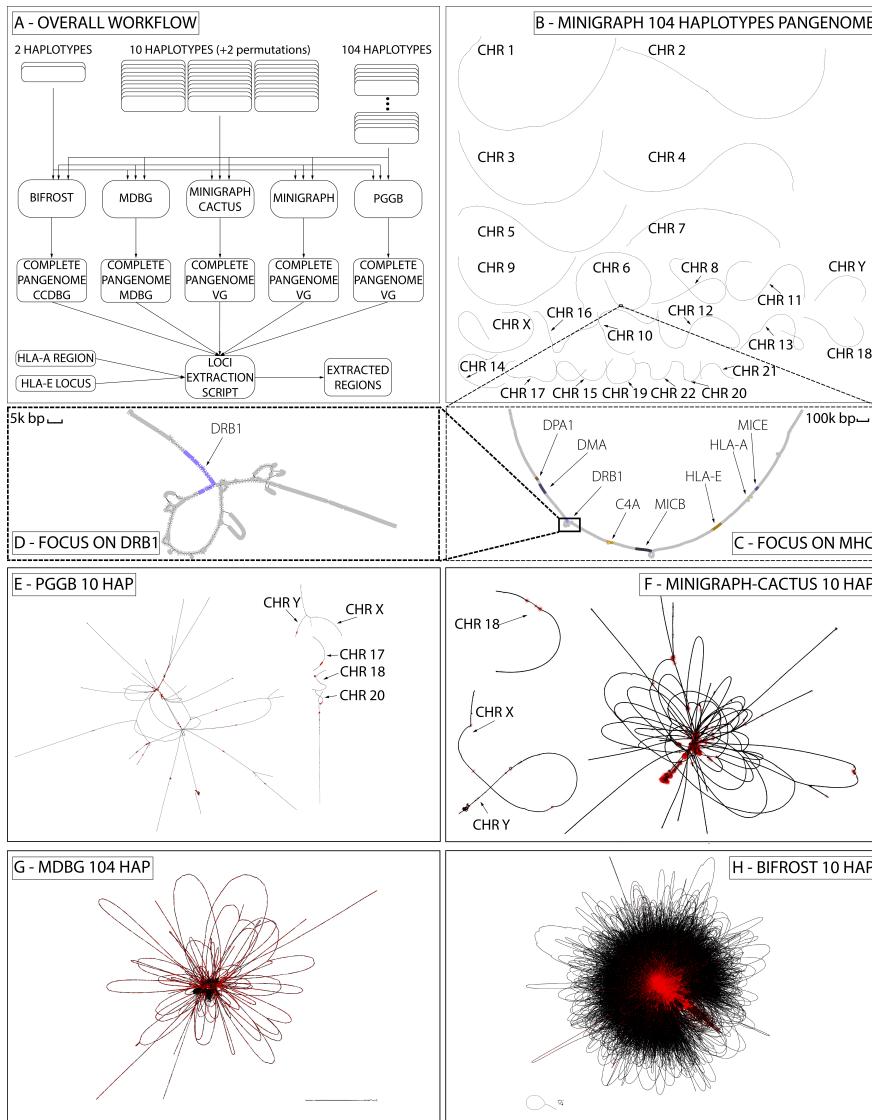

Figure 3.1: The complete pangenome construction scheme and visualization. **A**, The overall workflow, using 5 different tools on 3 different datasets; **B**, complete 104 haplotypes variation graph built by **Minigraph**; **C**, focus on part of HLA (MHC) region in chromosome 6 from panel B; **D**, focus on DRB1-5 locus of HLA from panel C; **E**, complete 10 haplotypes variation graph built with **pggb**; **F**, 10 haplotypes variation graph built with **Minigraph-Cactus**; **G**, 104 haplotypes pangenome **mdbg**; **H**, 10 haplotypes **Bifrost** dBG. 3. Comparing methods for constructing and representing human pangenome graphs

in term of disk space (for **Minigraph-Cactus**, 3.6 GB on H2 and 7 GB on H10). While **Bifrost** and **Minigraph** perform all computation in memory, **pggb**, **Minigraph-Cactus**, and **mdbg** store intermediate files on disk, taking comparable space to the input size (up to 3x for **Minigraph-Cactus**).

Different tools yield different pangenome graphs topologies

Graph metrics such as the number of nodes, edges and connected components provide useful insights on the level of detail of the represented variations and on the complexity and accessibility of the information inside the pangenome.

The number of graph nodes varies between 17,000 and 11 millions for the H2 dataset across all tools. In all cases, the number of nodes is at least 3 orders of magnitude smaller than the number of bases in the haplotypes, indicating that pangenome graphs are effective at compressing linear parts of the haplotypes. Tools which discard variations (**Minigraph** and **mdbg**) yield in the order of 10^4 – 10^5 nodes across all datasets, while tools which retain all variation (**Bifrost**, **Minigraph-Cactus** and **pggb**) yield in the order of 10^6 – 10^7 nodes. In all cases going from the H10 dataset to the H104 dataset increases the number of nodes by 5x, indicating that graph complexity grows sublinearly with the number of added haplotypes.

The number of connected components varies between 2 and 1402 across all methods and datasets, and the number of large components (i.e. those with more than 1% of total base pairs) varies between 1 and 30. If chromosomes were separated perfectly, pangenome graphs should contain exactly 24 connected components (one per nuclear chromosome, excluding mitochondria). **Minigraph** produces 24 large connected components as the number of chromosomes in the reference CHM13 v2.0 (25 including mitochondria). **Bifrost** and **Minigraph-Cactus** yield graphs with less than 25 connected components while **mdbg** and **pggb** have more than 25. In the **Bifrost** dBG, the vast majority of sequences (>99.99%) are in a single giant component, as chromosomes are joined because they share common k -mers. In **mdbg** such joining does not occur on dataset H2, which has 24 large enough components (each containing > 1% of bases), possibly due to the absence of long and similar enough regions between chromosomes. **Minigraph** does not map any mitochondrial sequence from the input haplotypes to the reference, while they do get included into **Minigraph-Cactus** graphs.

Even if it is common practice to analyze pangomes chromosome by chromosome [8, 17], in this analysis we purposely used entire genomes as input instead. This was done for two reasons: i) to highlight the scalability of the tools, and ii) because separating chromosomes prevents the identification of inter-chromosomal inversions, translocations, and transposable elements, even if most of the generated inter-chromosomal events are probably alignment artifacts. The effects of this choice can be seen in the **pggb** and the **Minigraph-Cactus** H10 variation graphs of Figure 3.1. In the **pggb** graph 19 chromosomes are linked into a single giant component, while chromosomes 17, 18, 20, X, and Y are

Table 3.1: Time, memory, final disk space, nodes, edges, total connected components and connected components with more than 1% of base pairs comparison of **Bifrost**, **mdbg**, **pggb**, **Minigraph** and **Minigraph-Cactus** for different number of haplotypes in input. **Minigraph-Cactus** times include the **Minigraph** graph construction step. **pggb** was not able to complete its execution on the largest dataset in more than 2 weeks thus it is not considered. **Minigraph-Cactus** failed to compute the 104 HAP dataset.

in other large components. This giant component consists of 25 M nodes that contain 83% of the total basepairs. The remaining 859 components represent only 4.7% of the total bases due to small sequences in the input haplotypes. In the **Minigraph-Cactus** graph all chromosomes are linked into a single giant component except chromosome 18 that is in a separate component, and the sexual chromosomes (X and Y) that are connected together into another component.

Interpretation of variation in pangenome graphs: focus on two HLA loci

The ability to detect and annotate variations among input haplotypes defines the scope of each pangenome graph construction method. Previous work [18] recommends to build graphs on a specific loci rather than the entire genome for the purpose of i) identifying genomic diversity and ii) mapping raw reads to divergent regions, specifically difficult-to-map repeats. Here we evaluate how pangenomes built from entire haplotypes represent specific biologically relevant loci.

Extraction of HLA-E and a complex HLA region from complete pangenome graphs We extracted from complete pangenomes the regions corresponding to

3. Comparing methods for constructing and representing human pangenome graphs

two loci of the Human Leukocyte Antigen complex, also known as HLA. These regions are highly medically relevant as they contain many disease-associated variants [19]. The first locus is the HLA-E gene, that is part of the nonclassical class I region genes, spanning 4,8 kbp and is relatively conserved across populations. It has been shown to have significant association with hospitalization and ICU admission as a result of COVID-19 infection [20]. The second is an HLA complex region comprising the HLA-A gene, part of the classical, highly polymorphic class I region. It is around 58 kbp long and contains the HLA-U, HLA-K, HLA-H, and HCG4B genes. We extracted these two regions from pangenome graphs using a custom script that yields a subgraph corresponding to a given set of sequences and their variation. The script uses a different recommended method for each of the pangenome graph types. In a nutshell, we extracted regions using exact coordinates when possible, and resorted to sequence-to-graph alignment otherwise (see Appendix Section "Loci extraction method" for details). While on variation graphs and mDBGs nearby nodes of an aligned region correspond to variations of the locus, this is not always true for standard dBGs. Extracting accurate and complete loci representation is an unsolved challenge for dBGs.

HLA-E: a low complexity region Figure 3.2 shows how the different tools represent HLA-E over datasets H2, H10 and H104. As expected, **Minigraph** does not detect any variation, since the SNPs that characterize the region are too small to be considered in the construction steps of their algorithm. **pggb**, on the contrary, has 2 SNPs in H2 and 3 in H10. **Bifrost** detects the same SNPs as **pggb** in H2 and H10. Both of them represent the exact same variations and render the same haplotypes paths. **mdbg** captures the heterozygosity of a large region containing the HLA-E locus as the number of samples grows. As the **mdbg** graph is built in minimizer space, nodes represent long genomic segments (in the order of hundreds of thousand of base-pairs). In H10 and H104, the minimizer-space representations of the haplotypes are identical; however, differences in flanking regions of the graph create variations that are captured in extra nodes that are also extracted in this region. On H2, **Minigraph-Cactus** detects 3 variations as the dataset used is different, containing the CHM13 reference and just one haplotype of HG006 (as in **Minigraph**), as discussed in Section "Datasets and haplotypes collection".

Figure 3.2 also illustrates how pangenome complexity grows with the number of genomes: the **Bifrost** H104 subgraph has the most variation across all methods, highlighting that dBGs represent variations exhaustively in large graphs. On the other hand, **pggb** has the most straightforward method for extracting subgraphs, and also represents variants exhaustively in datasets H2 and H10, but could not scale to the H104 dataset.

HLA complex locus: high complexity region Figure 3.3 is the counterpart of Figure 3.2 for the complex locus part. In this case the overall interpretability of

HLA-E LOCUS COMPARISON

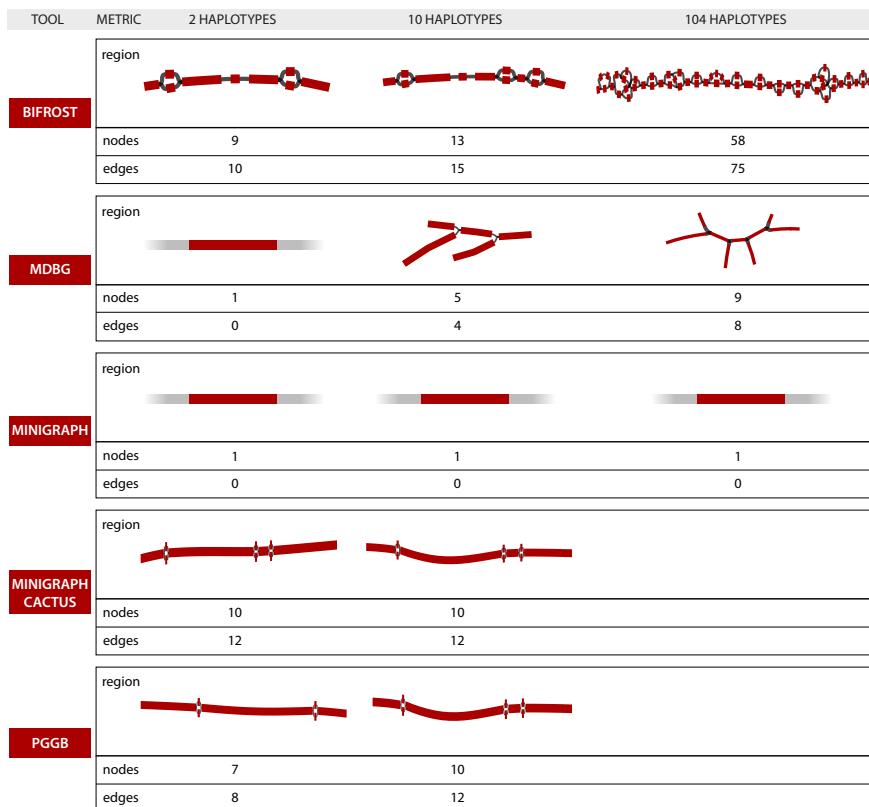

Figure 3.2: Representations of the HLA-E locus by five graph construction methods over three increasing large human pangenomes. Nodes highlighted in red contain part of the locus sequence. The numbers of nodes and edges displayed below each graph concerns the whole subgraph (both red and grey nodes). **Minigraph**, on H2, H10 and H104, and **mdbg**, on H2, have only a portion of one node highlighted since the 4.8k bp region is contained inside a single, long node.

3. Comparing methods for constructing and representing human pangenome graphs

the region is more challenging, as the number and the structure of the variations is different than in HLA-E. It is also more difficult to compare across tools. Base-level variations, e.g. SNPs, are not visually recognizable in Figure 3.3 in the methods that retain them (i.e. **pggb**, **Minigraph-Cactus** and **Bifrost**) due to the large sizes of graphs.

There are notable differences in how tools represent the variation, which is well-illustrated in the H2 dataset. While **Minigraph** renders H2 as a single sequence plus a large structural variant (SV) of $\approx 52\text{k bp}$, **pggb** separates it into two paths that differ by $\approx 54\text{k bp}$ in length. **Bifrost** represents a detailed bubble that contains many variations inside each path. In **mdbg**, even extracting the complete locus is a challenge as many of the subgraph nodes were not selected by our procedure. **Minigraph-Cactus** adds base level divergences between haplotypes on top of **Minigraph** SV graph.

These differences between representations are further accentuated in the H10 dataset. For it, **pggb** tends to separate the haplotypes into different paths, **Bifrost** renders consistently the same compacted representation and **Minigraph** neglects most of the small differences but is able to display accurately the general picture, and **Minigraph-Cactus**, as in H2, adds small variations on top of **Minigraph** structure.

Uncovering characteristics of graphical pangenome tools

The data structures generated by pangenome building tools are expected to facilitate comparisons between the input genomes. In addition pangenome graphs should be stored in such a way to be easily used by downstream applications. We identify 8 important features for pangenome graph construction tools: i) stability, ii) editability, iii) accessibility by downstream applications, iv) haplotype compression performance v) ease of visualization, vi) quality of metadata and annotation. Two other but important features, scalability and interpretability of produced graphs, were already discussed in Sections "Scalability and characteristics of pangenome graph construction tools" and "Interpretation of variation in pangenome graphs: focus on two HLA loci". Table 3.2 summarizes some of the following considerations on the relative strength of the tools.

Editability and dynamic updates As more high quality assemblies will be generated in the near future, haplotypes may be added to a pangenome, or replaced by improved versions. Updating an existing data structure instead of rebuilding it from scratch is both computationally and energetically efficient. However, many succinct data structures currently used in pangenome representation are static, i.e. cannot be updated. Some methods allow a restricted set of editing operations. **Minigraph** allows to add new haplotypes on top of an already built graph. **Bifrost** provides C++ APIs to add or remove (sub-)sequences, k -mers and colors from the ccdBG. **pggb**, using **odgi** [21], allows specific operations that delete and modify nodes and edges and add and modify paths through the graph. As **Minigraph-Cactus** can be opened with **odgi**, it

3. Comparing methods for constructing and representing human pangenome graphs

supports the same operations as `pggb`. The current `mdbg` implementation uses a dynamic hash table, but does not expose an interface that supports updates.

Stability Counter-intuitively, a pangenome graph construction tool may in some cases generate different outputs when executed multiple times with the same haplotypes as input. This *unstability* could be due to a permutation in the order of the sequences given as input, or non-determinism in the construction algorithm. Yet in order to facilitate the reproducibility of results, pangenome building tools should generate an unchanged output from the same set of input sequences, independently of the particular run or the order in which these are given. We performed two tests to evaluate tool stability: i) we run the tools 3 times using as input the same H10 dataset and ii) we run the tools twice on shuffled input sequences, i.e. changing the order of the haplotypes of H10.

`Bifrost` and `mdbg` constructed exactly the same pangenome on every test, as by definition, de Bruijn graphs are stable. `Minigraph` generates identical graphs on identical inputs, but generates slightly different graphs when the input is permuted. Indeed the construction algorithm of `Minigraph` is order-sensitive as it augments the existing graph structure by aligning the next given haplotype to it and adding divergent sequences. `Minigraph-Cactus` generates slightly different graphs on identical input. `pggb` generated slightly different graphs while maintaining the same haplotype sequences in the paths. The overall representation of the input genomes is therefore preserved, while the topology of the variation graph varies. The first two of the three phases of the `pggb` pipeline (all-vs-all alignment and graph imputation) produce the same result on different runs with the same input but differences arise when the order of the input haplotypes changes. Most of the differences in the graph topology are thus due to the final smoothing steps.

Accessibility by downstream applications To facilitate their adoption, pangenome representations should be easily processed by downstream analyses. De Bruijn graphs are challenging to analyze due to their high number of nodes, edges, and redundancy (the $k - 1$ -overlaps between nodes). Though De Bruijn graph representations usually support queries of presence/absence on nodes (as in `Bifrost`), they lack tools able to perform more elaborate analyses such as those discussed in Section "Interpretation of variation in pangenome graphs: focus on two HLA loci", e.g. incorporating haplotype information at the k -mer level. On the other hand, variations graphs with paths provide more flexibility, i.e. as in `pggb` and `Minigraph-Cactus` with the `odgi` visualization toolkit. Finally in `Minigraph`, which considers a narrower spectrum of variants, the absence of path information prevents haplotype-level analysis; haplotypes would need to be manually mapped back to the graph. The choice of the pangenome building tool depends on the envisioned application. `pggb` and `Minigraph-Cactus` graphs have been shown to outperform linear references for short read mapping, genotyping and RNA sequencing mapping [8]. As these two methods are complex pipelines based on multiple tools where parameters

have been carefully set, they can be more challenging to install and run than single integrated tools. **Minigraph** alone can also be used if the focus is on structural variation instead of SNPs or small indels, and to quickly produce a pangenome graph for complex loci visualization and interpretation. The dBG-based approaches show that, for example with **Bifrost**, they retain the same base-level information as more computational-heavy variation graph approaches, but the lack of tools to use them for analysis limits their adoption.

Haplotype compression Building a graph pangenome can be seen also as a way to store, compact and retrieve the input haplotypes. As the number of new assemblies is growing faster than the data storing capacity, pangenomes can potentially help save storage space. This is highlighted by the disk space reported in Table 3.1, which is consistently smaller than the sum of haplotype sizes for all methods and datasets.

In order to losslessly retrieve the input genomes from a pangenome, the representation has to store all variations from the original haplotype sequences as paths in the graph. **pggb** and **Minigraph-Cactus** fall into this category while the other three considered tools do not store paths, or do not consider all variations, thus they are lossy.

Of note, the GBZ tool [9] enables graph pangenomes that store paths in the GFA file format to be stored in a lossless compressed form. It uses a Graph Burrows-Wheeler transformation to compress the graph in a more efficient way than using gzip [9]. Using GBZ, the pangenomes generated by **pggb** and **Minigraph-Cactus** are losslessly compressed with space gains of 3.5-5x.

Ease of Visualization Visualizing large graphs which exceed hundreds of thousands of node is a challenge that exceeds the scope of pangenomics. The H104 pangenomes are difficult to visualize. Among the visualization tools considered by the Human Pangenome Reference consortium [6], only **Bandage** is able to display the **Minigraph** or **mdbg** H104 graphs, which contains a few million nodes. We reduced the number of nodes and edges of **pggb**, **Minigraph-Cactus** and **Bifrost** H10 graphs by collapsing isolated subgraphs representing SNPs or indels up to 10k bp (using the command `gfatools asm -b 10000 -u`).

Quality of Metadata and Annotation Augmenting pangenome structures with information from other omics data would increase pangenome relevance in biological discoveries. As biobanks are rapidly growing, more data is available on regulatory regions, transcriptomics, CNVs and other medically relevant traits [22, 23]. Pangenome data structures could leverage such information, and some of the considered tools offer basic functionality in this sense. **Bifrost** provides a function to link data to graph vertices through C++ APIs. **pggb** and **Minigraph-Cactus**, using **odgi**, offer annotation capabilities through insertion of paths or BED records. **Minigraph** and **mdbg** do not offer any annotation feature. Specifically, in order to enhance a pangenome graph with metadata (for example with genes and regulatory regions known variants), it is desirable

3. Comparing methods for constructing and representing human pangenome graphs

Table 3.2: **Relative strengths of five pangenome graph construction tools**

Explanation of rows: 1) efficacy of construction algorithm, measuring wall-clock time; 2) degree to which variants (e.g. SNPs) are retained; 3) ability of a tool to perform well on large datasets, both in comparison to other tools but also compared to smaller datasets; 4) ability to modify the produced data structure to add or remove haplotypes; 5) property of producing the same result irrespective of perturbations, such as permutation of the input order, and repeating the same run; 6) existence of tools (and operations) that can be applied to the resulting graphs; 7) whether input haplotypes information is retained by the tools, and if so, its space efficiency; 8) whether the entire graph can be directly visualized and interpreted; 9) easiness of ‘zooming in’ a specific genomic region and interpret variants; 10) summarizes the functionalities provided by the tools to annotate the pangomes with genomic data; 11) ability to share information between the graph and a linear reference.

to maintain compatibility with methods and data formats that use a linear reference. One could conceivably project data from a graph to a reference genome to continue downstream analyses using linear coordinates. A simple method to achieve this compatibility, in our view, is to store the reference genome of interest inside the graph pangenome that supports retrieving such a reference. Variation graphs built using **pggb** or **Minigraph-Cactus**, due to their locally acyclical and directed construction and their use of haplotype paths, store all the coordinates needed for such a task. Haplotype paths play an important role as they avoid additional mapping to the graph, by using the **odgitool** to extract or inject the required information. **Minigraph** does not store haplotype paths and requires mapping sequences to the graph to restore haplotype information. On the other hand, De Bruijn graphs, using associated color data, can record the membership of k-mers to a reference sequence, yet one cannot fully reconstruct a haplotype unless k-mers positions are also stored.

3.3 Discussion

Five state-of-the-art pangenome graphs construction tools were compared on the representation of up to 104 human haplotypes. The approaches significantly differ in terms of speed, graph size, and representation of variations. We find that

it remains computationally prohibitive to generate human pangenome graphs for hundreds of haplotypes, especially while retaining all variations. Each approach has its own set of strengths, and ultimately the choice of the method depends on the downstream application. In addition, several takeaway points emerged from our analysis.

First, our focused analysis of HLA loci revealed that de Bruijn graphs and variation graphs represent genomic variations equally well as pangenomes. This is of particular importance as also shown by the draft human pangenome references [8]: pangenomes are pivotal to trace complex and clinically relevant loci. While de Bruijn graphs are faster to construct, more stable, and scale better in terms of input size, the resulting graphs are challenging to interpret downstream. Variations graphs on the other hand are more practical to analyze at the expense of a less efficient construction step. Their visualization are more straightforward to interpret, mostly due to not having cycles, and provide insights into loci differences.

Second, we can highlight two categories of pangenomic methods that have distinct application domains. **pggb**, **Minigraph-Cactus** and **Bifrost** store all possible variations, and keep haplotype information as paths or colors. They provide a complete picture of the set of variations in the input genomes which makes them difficult to analyze. They can be used for a large variety of genomic analysis, as shown for **pggb** and **Minigraph-Cactus** [8]. **Minigraph** and **mdbg** generate 'sketched' pangenome graphs that consider only large variants, ignoring smaller differences, and are more efficient to construct and visualize. They can be used for large scale characterization of variation in population, as proven for bacteria [15].

Third, every tool possesses an exclusive set of features. **pggb** facilitates downstream analyses using the companion tool **odgi**. It allows to precisely extract and browse any locus of interest. It is the only tool that generates variation graphs without a reference. It also keeps a lossless representation of the input sequences. **Minigraph** generates a pangenome graph based on a reference sequence taken as a backbone. Its shines in the representation of complex structural variations, but does not include small or inter-chromosomal variations. The pipeline **Minigraph-Cactus**, that uses the **Cactus** base aligner, can be used to add small level variations on top of the **Minigraph** graph and to keep a lossless representation of the input sequences. **Bifrost** illustrates that classical de Bruijn graphs are scalable, stable, dynamic, and store all variations. However, extracting information from them remain a challenge. Lastly, **mdbg** is the fastest construction method which generates an approximate representation of differences between haplotypes. As discussed in Section "Accessibility by downstream applications", these features enable different genomic analyses and downstream applications.

3. Comparing methods for constructing and representing human pangenome graphs

3.4 Conclusions

In conclusion, our results highlight the strengths and weaknesses of current pangenome construction tools for human applications, with specific focus on how do they represent specific loci of medical relevance. We also provide insights on the features they possess and point out their best application domains. In our view, future directions for human pangenomes building tools should focus on tackling efficiency bottlenecks, aiming to represent hundreds to thousands of haplotypes. Representations should further be lossless and represent the input haplotypes as paths in the graph. Such features would unlock many other applications such as lossless compression of haplotypes and cancer copy number variant analysis. Finally, we recognize the need for more user-friendly tools that can be used by biologists and that can translate complicated questions into graph queries. While `odgi` begins to address these questions in variation graphs, other approaches have not yet provided user-friendly interfaces. A package similar to `odgi` for de Bruijn graphs would help fully realize their potential.

3.5 Methods

Datasets and haplotypes collection

In order to evaluate the state of current human pangenome representations, we sought to build a human pangenome that contains all publicly available high-quality human haplotypes. We collected from two different sources 102 different haplotypes from the genome of 51 individuals, and also used the two reference genomes, GRCh38 from the Genome Reference Consortium (GRC) [24] and CHM13 v2.0 cell line of the T2T Consortium [25]. Five haplotypes correspond to Google Brain Genomics DeepConsensus [26] assembly dataset: they are hifiasm assemblies of PacBio Hi-Fi reads corrected with DeepConsensus. The average of their N50 is 37,99 Mbp. The remaining haplotype assemblies as well as the T2T reference are from the Human Pangenome Reference Consortium (HPRC) year-1 freeze [6], and GRCh38 is from the GRC. Their average N50 is 40.3 Mbp. Since HG002 is contained in the DeepConsensus data, the HPRC HG002 haplotypes were not used. The origin and the sex of the individuals are diverse and provide a fair representation of the diversity in human population: out of 51 total individuals, 21 are males and 30 are females and they represent 14 different ethnic groups, from US to Africa and Asia. We did not perform any additional selection, regarding sex and ethnicity, on these public datasets as our main goal was to use as many genomes as possible. However, the HPRC stated that the genomes were selected to represent genetic diversity in humans [8].

To evaluate the scalability of pangenome construction tools, we created three datasets of increasing size: 1) 2 haplotypes from the same individual, HG006, 2) 10 haplotypes from 5 different individuals (HG002, HG003, HG004, HG006 and HG00735) and finally 3) all of the 104 haplotypes. To test whether the order of the input sequences matters, we considered various random orderings for the 10 haplotypes in Dataset 2. Since `Minigraph` needs a reference sequence as first

Table 3.3: **Description of the three datasets generated to test the scalability of the tools**

Data sources: ¹ Google Brain Genomics [27]; ² Human Pangenome Reference Consortium [28]; ³ 1000 Genomes Project [28]; ⁴ Telomere to Telomere Consortium [28].

Haplotypes	Project	Bases
2	Google ¹	5.9 Gbp
10	Google, HPRC ²	30 Gbp
104	Google, HPRC, 1KG ³ , T2T ⁴	313.6 Gbp

haplotype in order to correctly build the graph, we generated specific 2 and 10 haplotypes datasets with the first haplotype replaced by the reference genome CHM13. This was applied to the **Minigraph-Cactus** pipeline as well as it uses **Minigraph** variation graphs.

Pangenome graph construction tools

We evaluated tools that generate graph pangenomes as variation graphs and colored compacted de Bruijn graphs. Variation graphs are generally locally acyclic while de Bruijn graphs have cycles. In variation graphs, nodes represent sequences and edges represent immediate sequence adjacency without overlap. Variation graphs are generally easier to visualize and to interpret while challenging to construct at scale and, apart from **pggb**, require a reference genome. In de Bruijn graphs (dBG), nodes are k -mers (string of length k) and edges are $(k-1)$ -overlaps between nodes. In practice, dBGs are represented in a compact way where all nodes along unbranching paths are compacted into *unitigs*. The resulting graph is called compacted De Bruijn Graph, where nodes are unitigs and edges represent $(k-1)$ -overlaps. As shown in Figure 3.1, de Bruijn graphs result in large graphs that pose visualization and interpretation challenges, in particular as there is no alignment to a reference.

- **Bifrost** constructs dynamic, coloured compacted de Bruijn Graphs (*ccdBG*). It first generates a standard dBG using an efficient variant of Bloom Filters and then computes the compacted dBG from it. Colors, i.e. identifiers representing the sample origin of each k -mer are added by storing an array per k -mer. A human genome ccdBG typically consists of a single large connected component, as common k -mers are shared between chromosomes. This pangenome representation contains all the variations present in input sequences.
- **mdbg** builds a variant of de Bruijn graphs called a minimizer-space de Bruijn Graph (**mdbg**), which is efficient to construct as it only considers a small fraction of the input nucleotides. Color information is currently not

3. Comparing methods for constructing and representing human pangenome graphs

Table 3.4: URL, version, pangenome representation and parameters of the three analyzed tools.

pggb/0.2.0 used wfmask v0.7.0, seqwish v0.7.3 and smoothxg v0.6.1.

Tool	Github repository	Graph type	Version	Parameters
Bifrost	pmelest/Bifrost	De Bruijn graph	1.0.5	-k100 -c
pggb	pangenome/pggb	variation graph	0.2.0	-p 98 -s 10000 -k 311 -G 13033,13117 -O 0.03 -v -t 8 -T 8 -A -Z
Minigraph	lh3/Minigraph	variation graph	0.18	-cxggs
Minigraph-Cactus	ComparativeGenomics Toolkit/cactus	variation graph	2.2.3	-maxLen 10000 -delFilter 10000000
mdbg	ekimb/rust-mdbg	De Bruijn graph	1.0.1	-k 10 -d 0.0001 -minabund 1 -reference

supported in the implementation. Similarly to Bifrost, a **mdbg** also typically represents a human genome as a single large connected component, albeit with orders of magnitude less nodes. Minimizer-space de Bruijn graphs mostly discard small variants, yet are sensitive to heterozygosity which creates branches in the graph.

- **Minigraph** constructs a directed, bidirected and acyclic variation graph iteratively by mapping new haplotypes using a combination of the minimap2 tool and the graph waveform alignment algorithm. The first input sequence acts as a backbone for the whole representation. The sample(s) of each node are stored in a rGFA output file. **Minigraph** considers only variations longer than 50 bps hence it is oblivious to isolated SNPs and small indels: even if it produces base-level alignment for contigs, the graphs are not a base-level resolution. The resulting graph is divided into connected components that correspond to the chromosomes present in the first given input genome.
- **Minigraph-Cactus** is a variation graph construction pipeline that combines **Minigraph** to generate a structural variations graph and **Cactus** base aligner to generate base-level pangenome graphs of a set of input assemblies and embg: The definition of as changed! Check your packages! Replacing it with the kernel definition on input line 145.ed haplotypes paths. **Cactus** [16] is a highly accurate and scalable reference-free multiple whole-genome alignment tool, that in this pipeline considers the reference sequence used by **Minigraph** to ensure that the resulting variation graph is acyclic. The final graph is further normalized using GFAffix[29]. The pipeline allows to generate multiple graphs, one for each chromosome, or produce a single graph that includes inter-chromosomal variants.
- **pggb** is a directed acyclic variation graph construction pipeline rather than a single tool. It calls three different tools: pairwise base-level alignment of haplotypes using wfmask [30], graph construction from the alignments with seqwish [31], graph sorting and normalization with smoothxg and GFAffix [32, 29]. The resulting variation graph represents variations of all lengths present in the input sequences.

Supplementary Information

Benchmark infrastructure

Running time of pangenome construction tools was measured as wall clock time and peak memory as maximum resident set size using the `time` command. Other metrics were obtained with custom Python scripts. All benchmarks were performed on a Supermicro Superserver SYS-2049U-TR4, with 3 TB RAM and 4 Intel SKL 6132 14-cores @ 2.6 GHz, using 8 cores.

TwoPaCo

We did not consider **TwoPaCo** as it is redundant with **Bifrost**. Both methods construct the same de Bruijn graphs. **TwoPaCo** is a method for constructing ccdBGs by finding junction k -mers at the boundaries of unitigs or in branching nodes. It consists of two main steps in which it approximates the dBG with a Bloom filter in order to reduce the size of the problem and then runs a two pass highly parallel algorithm on it. It constructs ccdBGs similarly to **Bifrost**. **Bifrost** is faster, supports edit operations, and accepts also reads other than assemblies as input. We tested both tools on NCBI datasets from three different known human variation regions part of the human leukocyte antigen (HLA) complex: HLA-A, MICB and TAP1. These loci have different number of sequences and have complexity and length. The resulting graphs have exactly the same k -mer content and substantially equal topology. The difference is that **TwoPaCo** considers sequences with IUPAC 'N' bases while **Bifrost** does not and that in some cases **TwoPaCo** renders some unitigs split in two or more consecutive nodes.

Loci extraction method

For **Bifrost** and `mdbg` graphs, nodes corresponding to the input sequences are identified with **GraphAligner** [33] and the subgraph is extracted using the **Bandage** *reduce* function. As the aligned nodes are not expected to represent the full diversity of the population in the pangenomes, the considered portion of the graph contains also nodes up to a certain distance from the aligned ones: 1 for `mdbg` and 3 for **Bifrost**. This number is based on the size of the sequences spelled by the nodes and on the considered variations. Artifacts, mostly tips, that are not part of the locus of interest are removed with a custom python script. For **Minigraph** generated graphs, the **Minigraph** own alignment function has been used to identify the nodes and then **Bandage** is used to extract the subgraph. For `pggb`, first we generate a bed file of the position of the region of interest in every haplotype used to construct the graph. The ranges are derived from aligning them to the locus sequence(s) using `minimap2` [34]. The graph corresponding to the region is then extracted using the `odgi extract` and `odgi view` functions. For **Minigraph-Cactus** we use the same strategy as `pggb`, with

3. Comparing methods for constructing and representing human pangenome graphs

the difference that the bed file is only for the reference CHM13, present in the graph.

The annotation of the specific loci in the subgraph is done using nodes from the alignment with **Minigraph** or **GraphAligner** to the subgraph. This makes it possible to highlight multiple sections in the region, as, for example, genes and pseudogenes of interest.

Availability of data and materials

The scripts used to generate and analyse the pangomes can be found at [35][36] under MIT license. Google Brain Genomic assemblies can be found at [27]. HPRC assemblies, CHM13 and GRCh38 can be found at [28].

Funding

R.C was supported by ANR Full-RNA, SeqDigger, Inception and PRAIRIE grants (ANR-22-CE45-0007, ANR-19-CE45-0008, PIA/ANR16-CONV-0005, ANR-19-P3IA-0001). This project has received funding from the European Union's Horizon 2020 research and innovation programme under the Marie Skłodowska-Curie grants agreements No. 872539 and 956229.

Author's contributions

FA, YD and RC conceived and designed the project. FA implemented the scripts. FA and PL ran the experiments. FA, YD, PL and RC wrote the paper. The authors read and approved the final manuscript.

3. Comparing methods for constructing and representing human pangenome graphs

3.6 Perspectives

The results of the work outlined in this section suggest several directions for future investigation and software development: they can be divided into a few axis. On one side, the scripts and software that I developed to produce the analysis of this paper could have been extended into an automatic reproducible pipeline. By integrating the code into platforms like nextflow or Snakemake, this could become a benchmark for current and future pangenome tools, as, at the moment, there is no other way to independently compare the output of tools that produce variation graphs and dBGs.

On another side, there are many more features that could be added to the analysis workflow to produce a more in-depth and accurate description of the resulting pangenomes, like node (sequence) length distribution, node degree distribution, count of SNPs and indels. It is important to stress that detection of specific pattern of variation is non-trivial in data-structures like dBGs. Finally, another experiment that could be done is to convert, using path information, the variation graph into a ccdBG, to compare against a ccdBG built directly from the input sequences: this would allow to verify if the information stored into the two data structures is equivalent.

Another very interesting avenue would be to develop a tool that enables complex information extraction from ccdBGs. Construction tools usually offer commands or apis to perform simple absence/presence queries, that are mostly useful when they are used for metagenomic purposes but offer less actionable insight in pangenomics analysis. An idea that I have started exploring during this PhD is to extract a subgraph of a ccdBG that represent a locus or gene of interest in the whole dataset provided as input.

Finally, it would be very useful to define a ccdBG output color format that every tool should also use to output the colors, like gfa is used to output graphs. As of now, each tool implements its own binary format for color storage, discouraging downstream analysis software development, as it would be bound to specific construction tools and not the common data structure used.

3.7 Building a *Lodderomyces elongisporus* pangenome reference: overcoming current limitations.

Here we present another example of pushing the boundaries of variation graph pangenome building strategies, precisely in producing a graph that can represent inter-chromosomal events, like rearrangements, for the medically interesting yeast strain of *Lodderomyces elongisporus*. We show also how a pangenome based approach can help produce a more comprehensive insight of such events than a linear genome based one.

The work presented here is also in part a team effort with other PhD students and researcher I was co-leading with Daniel Doerr during a winter-school organized by my consortium: Simon Heumos, which I would like to thank for the discussion we had on the construction of such graphs and Nicola Rizzo. Most of the results and findings reported here are mostly my own, subsequent, work.

The following sections will explain the process needed to produce custom, biologically-significant and biologically-driven pangenome graphs of a yeast strain with the current state-of-the-art tools and offer insights on workarounds that can be used in cases with special needs, where current tools features limit the analysis that can be done. This will also show how pangenome models can offer more powerful tools to analyze specific variation in a group of similar genomes compared to linear reference based ones.

In this specific case, the goal was to produce a variation graph that considered, and showed, the long chromosomal translocations that were noticed by the team that produced the assemblies from short and long reads. Chromosome-crossing syntenies for multiple contigs in alignment hits of chromosomes C, G, and H, were detected, suggesting that they could correspond to a singular same recombination group. This finding was consistent with an independent SNP-based genomic study. It was performed on the isolates of a fungemia outbreak in a neonatal intensive care unit in Delhi between 2021 and 2022 and it noticed that this translocation events are more frequent in hospital and patient associated populations than in fruit ones [37].

In summary, the work here presented will be organized as follows:

1. Brief characterization of *Lodderomyces elongisporus* genome and relevance;
2. Pangenome graphs constructed and their utility;
 - a) Determining the chromosomal communities from the assemblies to generate a variation graph of interest;
 - b) Producing a variation graph with `pggb`;
 - c) Producing a variation graph with `Minigraph-Cactus` by customizing the pipeline and the data;
3. Representation of translocation events in variation graphs;

3. Comparing methods for constructing and representing human pangenome graphs

3.7.1 *Lodderomyces elongisporus*: genetic characteristichs, interest and used data

Lodderomyces elongisporus is a diploid yeast that has been isolated from, among many sources, humans and it is recently emerging as pathogenic. It is phylogenetically placed in the Candida clade and the size of its genome is usually between 15 and 16 Mb, 2 orders of magnitude smaller than a human genome [38]. Its DNA is organized into 8 chromosomes, that here will be referred in alphabetical order and decreasing size A to H, from around 3.5Mbp of chr A to 800 Kbp of chr H, plus a 35 Kbp mitochondrial DNA. Our analysis shows that it has a stable core genome of 13Mbp, as shown in section 3.7.4. Increasing reports of (mostly bloodstream) infection in mainly immunosuppressed adults makes it an increasingly important subject of studies[39, 40, 41, 42]: it also got recent attention when an outbreak was reported occurring in a neonatal ICU in Dheli, India from September 2021 to February 2022 with 1 death[37].

11 samples sequenced by us were assigned names with one letter in alphabetical order from A to K followed by a number greater or equal than 0 that denoted the quality of the assembly (with 0 draft to 2 manually curated). More in depth statistics like the number of sequences, N50 and others are shown in table 3.5. Moreover, one sample, B2, for which a member of the consortium produced a high quality assembly after intensive manual curation, was used as relative reference in the cohort. Another sample, J2, was also fully resolved into chromosomes while the others were assembled into contigs.

3.7.2 Building ad hoc pangenome reference

We produced a dBG from all 11 assemblies described in table 3.5 using **Bifrost**, but their usefulness remains limited for visual analysis of complex biological events interpretation and study.

Figure 3.4a shows the visualization of the dBG for k -mer length equal to 25: repetitions make the visualization of the graph challenging. This is the same phenomenon previously described for human genomes, as better insight can be acquired when just a small region is visualized. De Bruijn Graphs can instead be useful for to produce quite straightforward whole-genome alignment- and reference-free phylogenetic analysis in a fraction of time required by competitor methods that use all vs. all alignment. The tool **SANS serif** [43] can process directly a **Bifrost** generated ccDBG to estimate the phylogenetic splits between the genomes contained in the graph. Figure 3.4b shows the visualization of the phylogenetic network produced by **SANS serif** using the tool **SplitsTree** [44]. By adding another genome from a close species it is possible control that the dBG-based analysis provides correct results. Figure 3.4c shows the phylogenetic network when an assembly of *Lodderomyces Beijngensis* is added to the graph: the new genome is very separated compared to the other ones from the same species. This results shows how dBGs are a powerful model when applied to specific applications.

Given high quality assemblies generated by the sequences of these 11 samples,

we decided to also build a pangenome graph with small variant resolution using **pggb** and **Minigraph-Cactus**, in a similar way to what has been done with the Human Draft Pangenome Reference [8]. It is important to notice that in order to produce the best biological correct result, several rounds of parameter tuning and manual curation are needed, with knowledge far superior of the one of a first-time user.

The first step to build such pangenomes is to divide the genome assemblies into communities of sequences belonging to chromosomes.

3.7.2.1 Determining chromosomal communities

Variation graphs construction pipelines use mapping or alignment between the input set of genomes to infer graphs. Their first step consists in grouping the sequences from the assemblies into communities representing a chromosome in order to run a single computation instance and produce a separate graph for each of them. The final graph is then given by joining together the output of each group. This means that without any pre-processing, no inter-chromosomal event can be detected.

In this specific use-case, in order to identify inter-chromosomal events, contigs associated to any of the 3 chromosomes conjectured to be part of the rearrangement had to fall into the same community and be provided together in input to the pipeline. This would ensure that, if such rearrangement exists, it would produce a feature in the graph that would show as a tangle between the chromosomes.

As the rest of the assemblies, with the exception of the J2 sample, were not resolved into single chromosomes, each of them was aligned to the reference B2 using **wfmash** alignment segment size of 10k and 95% sequence identity (and lower segment size, 90% sequence identity if unmapped). The identity scores of the alignment of the genomes to the reference B2 assembly is shown in figure 3.5. From this alignment, contigs were assigned to the chromosomal community to which they best mapped. Finally, chromosomes C,G,H were grouped manually into a single community.

3.7.2.2 Producing a variation graph using **pggb**

As **pggb** uses all-vs-all alignment of a collection of sequence as first step to infer the graph, it enables the representation of recombination among chromosomes placed inside the same community, as seen also for human acrocentric chromosomes [45].

The **nextflow/pangenome** (**pggb**) pipeline was run for each of the identified chromosomal communities to produce a first pangenome representation of the 11 yeast strains. The tangle visible in figure 3.6 clearly shows the recombination happening between the three chromosomes. This work was mainly done by Simon Heumos and the graph shown in figure 3.6 is the result of more than 25 rounds of parameters tuning. The detection of the event with a variation graph using **pggb** encouraged the effort to produce a similar representation

3. Comparing methods for constructing and representing human pangenome graphs

with **Minigraph-Cactus**, a pipeline that is not designed to construct grouped chromosomes pangenomes.

3.7.2.3 Overcoming Minigraph-Cactus limitation by modifying both the data and the pipeline

In order to produce a graph that represents variation between multiple chromosome with **Minigraph-Cactus**, a custom pipeline has to be used. **Minigraph-Cactus** communities are implicitly inferred by the first step, performed by **Minigraph**. For this tool, the chromosomes present in the first reference genome given as input are used as communities and backbone for the whole graph and no sequence can be both assigned to different chromosome. This is an intrinsic characteristic of **Minigraph** and cannot be changed with input parameters: it means that there is no feature to have chromosome C,G and H considered together in input.

To try to overcome this limitation of the approach we tried to produce a graph that respected the condition of having the three chromosome inside the same connected component, at the cost of producing a representation that was not biologically correct. We therefore produced a chimeric contig consisting of the concatenation of the three chromosomes assemblies of the B2 sample. The rationale was to provide the 3 chromosomes chained together as a single backbone in the **Minigraph** construction step. This would allow sequences to be mapped to any of chr C, G and H to be considered together in the subsequent steps of alignment and graph the **Minigraph-Cactus** pipeline. The expectation was to therefore produce a graph that showed the recombination from the mapping of the contigs of the other genomes.

By building a graph using **Minigraph** with the chimeric chromosome CGH and all the contigs of the other genomes assigned to chromosome C, G and H does not represent any recombination event, as can be seen in figure 3.7a. This was somewhat expected, as it is known that **Minigraph** does not also consider inversion between genomes. When the complete modified pipeline of **Minigraph-Cactus** is run, it is possible to see the tangle between the chromosomes, as shown in figures 3.7b 3.10.

3.7.3 Representing translocation events from groups of genomes

Applying simple community separation on the all vs all alignment of the contigs, like the one suggested in the manual of **pggb**, does not help confirming the hypothesis, mainly because of segment length selection. Figure 3.8 shows community detection using Louvain algorithm on the contig network inferred by all vs all alignment. This inter-chromosomal rearrangement is instead detectable using linear whole-genome assembly based tools. By aligning J2 to the relative reference genomes B2 with **wfmash** and then looking for syntenies and rearrangements with **SyRI**, it is possible to detect syntenic path (longest set of co-linear regions), structural rearrangements (inversions, translocations, and duplications) [46]. Figure 3.9 shows the detected rearrangements and duplications

between the 3 chromosomes using `plotsr` [47]. While figure 3.9 shows in a clear way the kind of inter-chromosomal variation between the 2 strains, `SyRI` does work only with genomes resolved to chromosome level. This means that such analysis is not possible on the whole cohort using standard linear reference tools. The only way to see the rearrangement for those assemblies is through a variation graph built with `pggb` and `Minigraph-Cactus`. This result shows the power of the pangenome model to analyze a set of genomes.

3.7.4 Estimating core genome and pangenome growth

Finally, pangenome graphs are also useful to quantify the part of the genome that is shared between genomes (what is called core-genome) and the parts that are mostly shared or private to each one. It is also interesting to estimate its growth, i.e. to measure how much the total genomic content grows with the increase of the size of the sample. These metrics can be obtained by using the tool `Panacus` [48]. `Panacus` is a tool that calculates coverage distributions of countable elements in variation graphs: it uses paths to detect how many genomes are associated to any node, edge or basepair of the pangenome graph. From these distribution it computes the pangenome growth and core curves as function of the number of genomes.

Calculating these metrics can be used to validate that the two variation graphs built with `pggb` and `Minigraph-Cactus` agree on the underlying genetic distribution of the input sample.

Figure ?? shows very concordant metrics for the two variation graphs. First, they show similar basepair coverage histogram, that highlight a great portion of genome shared by all the samples, and a non-negligible share of sequences that are private to each genome (1.5Mbp in total). Secondly, both growth curves show similar pattern, that seems plateauing. This is also highlighted by the fraction of new base pairs introduced by each sample, that decreases from 700k new basepairs with the new sample to less than 142k base pairs in on the 11th genome. Finally, the core pangenome can be estimated by the basepairs that are spelled by all the genomes in the graph: the computed value for the 11 samples is 13,2 Mbp for `pggb` and 13,6 Mbp for `Minigraph-Cactus`. The variability in the results are expected and due to different graph construction methods.

3.8 Conclusion and Perspectives

The work presented above shows how pangenomes can serve as analysis platform of samples from same-strain yeast.

dBG-based tools currently offer a limited range of possibilities, especially for lower sample sizes. They best serve as fast and memory-efficient container for large amounts of data that require simple interrogations like absence-presence queries. This model can nevertheless help answer simple biological questions on such small samples, like phylogenetic analysis shown in figure 3.4b.

Variation Graphs on the other side are powerful and very useful on few genomes

3. Comparing methods for constructing and representing human pangenome graphs

analysis as they can be built quickly enough and provide a well-established platform for downstream analysis tools. On the other side, there is still need to very labor-intensive manual revision of the output graphs to find the input parameters that produce the best result, as it took more than 25 rounds to find the best **pggb** parameters to produce the graph shown in figure 3.6. As they are produced on heuristics and not on mathematically defined concepts, each variation graphs-construction tool produces different results: in figure 3.11, it is possible to see the difference 1d-representation of the small chromosome E between **pggb** and **Minigraph-Cactus**. Finally, in order to detect the inter-chromosomal rearrangement with **Minigraph-Cactus** as in figure 3.10, I had to rewrite the pipeline and modify the input data.

Apart from the aforementioned limitations, that show how such methods are still more prototypes than sound and established tools, this analysis shows how much potential there is to improve the current state-of-the art in genomes analysis. Linear-sequences tools are based on well-established genome-to-genome comparison methods that fail to adapt to heterogeneous data, like different levels of assembly quality. As **SyRI** fails to detect rearrangements on genomes that are not assembled to the chromosome level, variation graphs are able to show the variation among all samples, even if the majority of the genomes contain contigs. This work is another display of the great potential pangenome approaches have. In the future it would be very interesting to build pipelines or develop tools that enable visualizations and straightforward analysis from variation graphs or ccdBGs to the same level as the current linear-genomes tools. As I have already conceptualized some possible approaches for ccdBGs, in the future it would be useful to develop simple prototypes and test how fast and precise these would be.

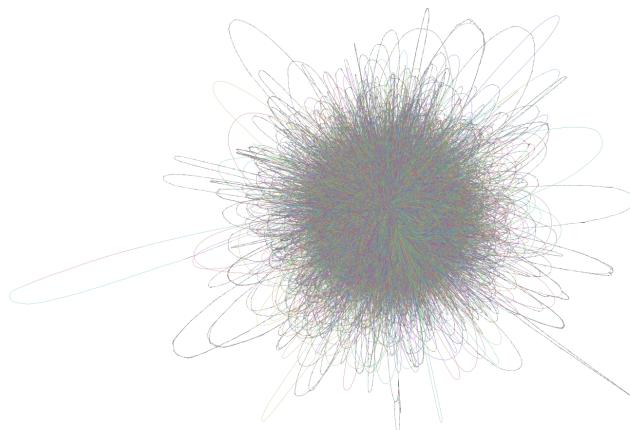

In the future it would be very informative to produce a more comprehensive report of the work done by my group and me, together with the other groups that worked on analyzing these novel *Lodderomyces elongisporus* samples, to offer a comprehensive view of how specific pangenomes can be built and used to provide improved genomic analysis capabilities.

Table 3.5: *Lodderomyces elongisporus* samples assembly statistics. N50n represents the number of sequences that contain 50% of the assembly.

There are no unknown nucleotides or gaps (any arbitrary stretch of Ns - i.e. unknown nucleotide). Metrics obtained using assembly stats software from Sanger Institute [assemblystats].

3. Comparing methods for constructing and representing human pangenome graphs

(a) **Bandage** visualization of the pangenome dBG of the cohort of 11 *Lodderomyces elongisporus* strains. As for human genomes, visualization of the whole data offers no particular insight, apart from the large variations visible on the rounded parts away from the dense part.

(b) **SplitsTree** visualization of the phylogeny network generated using **SANS serif** from the ccdBG constructed using **Bifrost**.

(c) Phylogeny network of the 11 *Lodderomyces elongisporus* strains plus one genome of *Lodderomyces Beijngensis* shows the ladder separated on the right while the group of figure 3.4b compacted on the left. As they are two different species, although close in the Candida/Lodderomyces clade[**lodelo_genomes**], this result provides positive control for the phylogeny network generated using **SANS serif** from the ccdBG constructed using **Bifrost**.

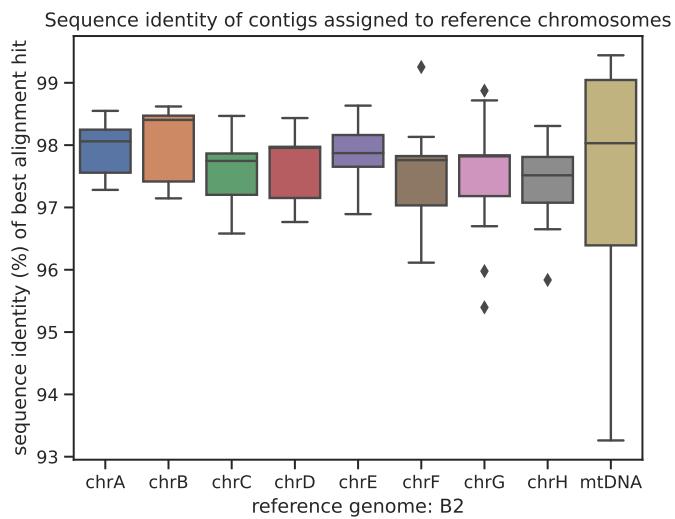

Figure 3.5: Sequence Identity of contigs assigned to reference chromosomes.
Image produced using a pipeline developed by Simon Heumos.

3. Comparing methods for constructing and representing human pangenome graphs

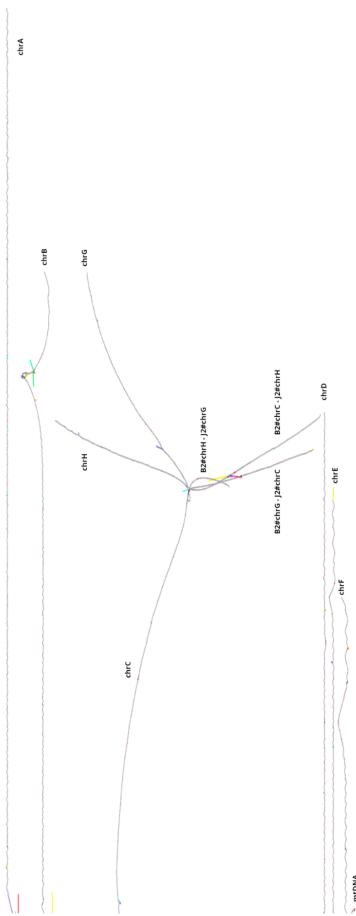

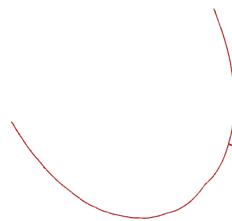

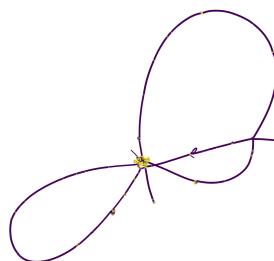

Figure 3.6: `gfaestus` visualization of the `pggb` variation graph of the 11 *Lodderomyces elongisporus* samples. Image produced by Simon Heumos.

(a) Graph of chimeric chromosome CGH from sample B2 and all the contigs of the other genomes aligning to it produced with **Minigraph**. The graph is linear and no inter-chromosomal event is visible.

(b) The graph after all the other steps of the **Minigraph-Cactus** pipeline, colored by depth, after simplification of variants < 1kbp using the command `gfatools asm -b 1000 -u`. The large recombination event is now visible.

Figure 3.7: Difference in output between **Minigraph** and **Minigraph-Cactus** of the chimeric graph produced to visualize the inter-chromosomal event between C,G and H.

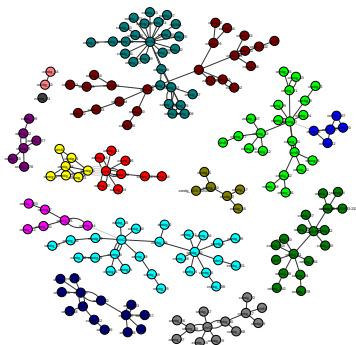

Figure 3.8: Community partition of the contigs based on all-vs-all alignment scores.

3. Comparing methods for constructing and representing human pangenome graphs

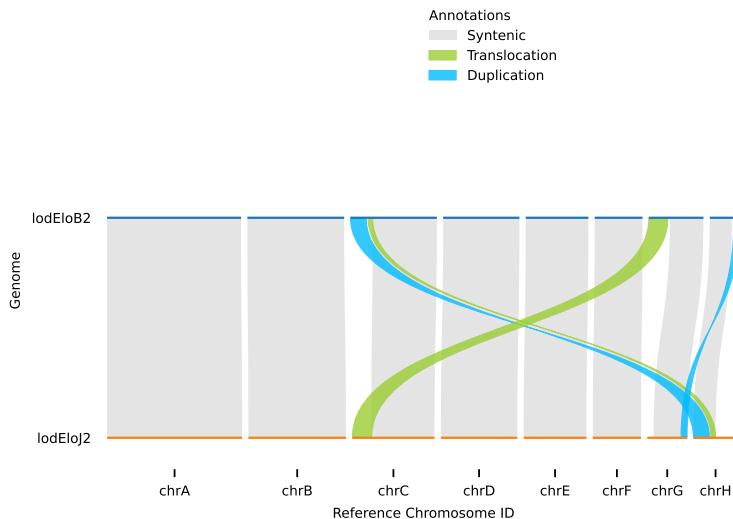

Figure 3.9: `plotstr` visualization of the inter-chromosomal recombination detected using `wfmash` and `SyRI`.

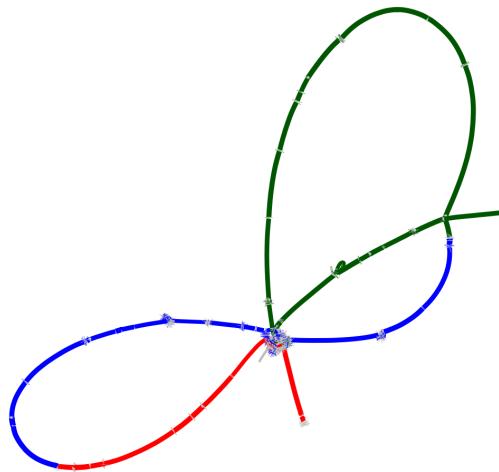

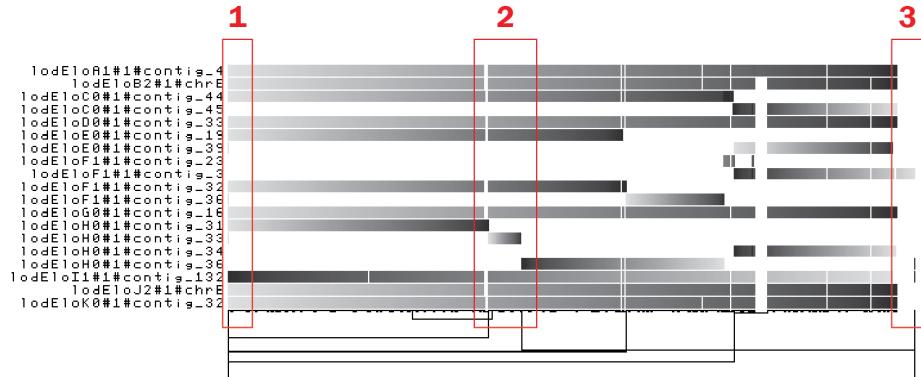

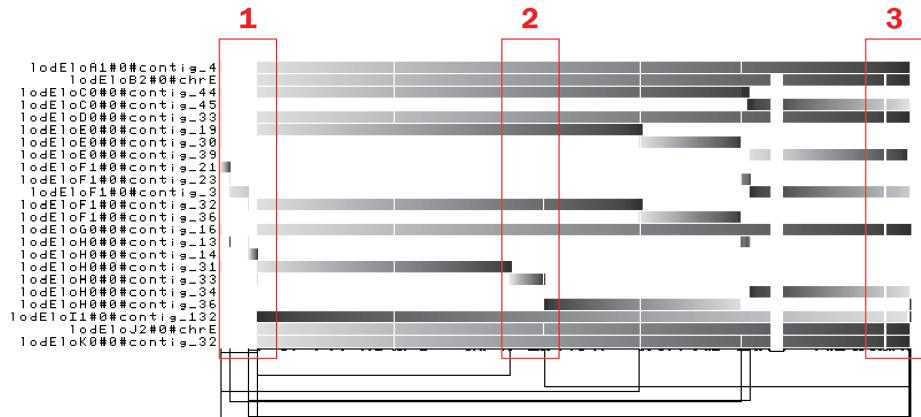

Figure 3.10: `Bandage` visualization of the tangle of chromosomes C, G and H in the `Minigraph-Cactus` variation graph. Nodes are colored based on `Minigraph` alignment of chromosome C (dark green), G (blue) and H (red) of the reference assembly B2. The three chromosomes are bound together because of the construction.

(a) One dimensional visualization of the variation graph built with `pggb`, containing 19 contigs from the assemblies, selected before construction using all vs all alignment data.

(b) One dimensional visualization of the variation graph built with `Minigraph-Cactus`, containing 23 contigs from the assemblies, selected automatically by the pipeline.

Figure 3.11: One dimensional visualization of chromosome E variation graphs of `pggb` and `Minigraph-Cactus` using `odgi`. Differences are highlighted by the three red boxes.

3. Comparing methods for constructing and representing human pangenome graphs

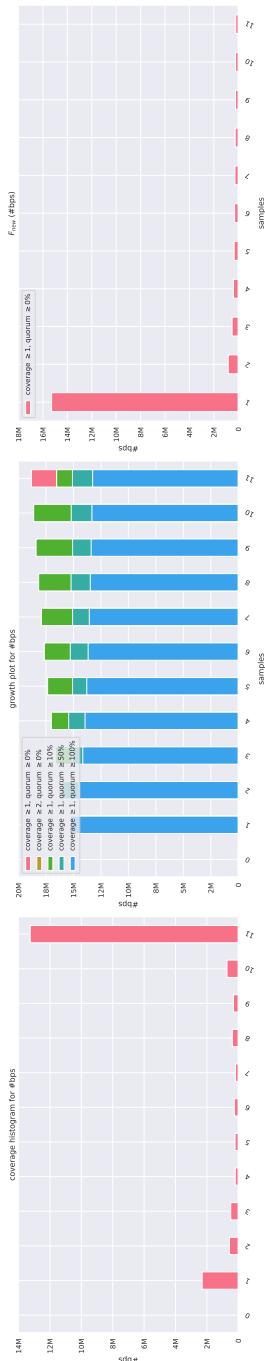

Figure 3.12: Pangenome core and growth of **pggb** variation graph. The bottom figure shows the coverage histogram in number of basepairs, the middle one shows the evolution of the pangenome growth and core by increasing sample size and the top one the new basepairs added by each new genome in the sample.

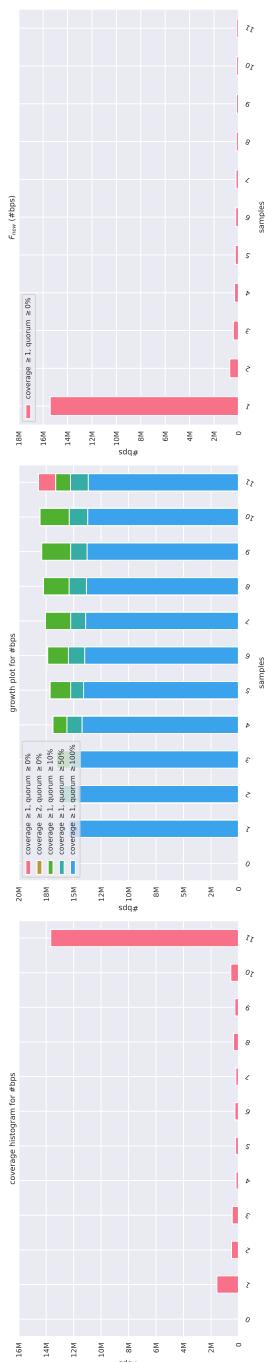

Figure 3.13: Pangenome core and growth of **Minigraph-Cactus** variation graph. The bottom figure shows the coverage histogram in number of basepairs, the middle one shows the evolution of the pangenome growth and core by increasing sample size and the top one the new basepairs added by each new genome in the sample. **69**

Chapter 4

Reducing the complexity of De Bruijn Graphs for Pangenomics

4.1 Introduction: too big, too complex, too difficult to use

As discussed in the previous section of this manuscript, the construction of pangenome as variation graphs is based on an alignment step that is well known to be accurate but computationally costly. Even if recent advances on alignment algorithms and tools, like the *wavefront* algorithm [[wavefront](#)], have provided improvement in the time and space complexity, the computation time is bound to the sequence length. As this is a feasible approach for curated analysis of small samples of large genome organisms, it is not considerable for large collection of hundred of thousands of bacteria or thousands of mammals. Finally, the alignment step implicitly requires high quality complete assemblies to produce reasonably connected graphs, while there is now available a large quantity of raw (or lightly processed) data that can be used in pangenomics applications [[serratus](#), [logan](#)].

For this reason, k -mer based approaches provide a solid alternative: as the used k -mer length is usually relatively small (from 21 to 100), they can be used also on more fragmented assemblies or directly on raw sequencing reads. Such tools usually use different data structures to represent internally in an efficient way a DBG model. Implementations decisions are often bound to optimization compromises made to achieve different goals: disk compression to produce small-sized indexes from large collections; fast query time of a novel sequence to understand in which genomes it is also present; fast construction of the model from input; time/memory computational trade-offs. In any case, the computational resources to produce cDBG from a set of input genomes are, as shown in the previous chapter, quite lower and the tools scale to significantly larger collections.

Even if DBG-based tools offer promising results when building pangenome graphs in terms of scalability and computational cost their use in pangenomics is still low mainly due to:

- limited operations that can be performed on the data except basic k -mer interrogations on a query sequence to understand in which other genome in the model they are present;
- the complexity and dimension of the cDBGs that makes visualization and other high-level operations very difficult to be achieved.

For this reasons:

4. Reducing the complexity of De Bruijn Graphs for Pangenomics

- total graph visualization is not achievable for large collections (except in the case of minimizer dBGs introduced in the previous chapter, that can give still relatively limited biological insight);
- large and complex regions visualization is also very difficult to achieve and gives results often confounded by repetitions, like seen in the previous chapter;
- downstream applications are limited by the need of in-between tools that use construction methods to achieve a representation and then use queries to infer relevant information. This is also relatively discouraged by the fact that most tools have little to no documentation and different api schemes.

4.2 DBG-based tools for pangenomics

4.2.1 Requirements

4.2.1.1 Bacterial pangenomics

4.2.1.2 Human pangenomics

4.3 Data structures to represent pangenomes as sets k -mer sets

Contemporary analysis of sequencing data, i.e. the *reads* that are generated from the processing of sequencing a biological sample, is mostly performed by string algorithms. These algorithms transform the raw string data using ad-hoc data structures to enable users (mostly bioinformaticians in biology-oriented research institutes or hospitals) to elucidate a particular question. Software based on these algorithm is, most of the time, just the beginning of more elaborated pipelines.

One subset of the many applications of string algorithms is the generation of data structures (i.e. rearrangement of data) that provide efficient storage of the data and that allow very fast interrogations of the absence, presence or (abundance count) of a particular string in it, i.e. checking if it is present in the data and if so, how many times. These processes are known as indexing and querying. The datasets to index in the use cases elucidated in the section above are in the order of tens of TeraBytes of raw data.

A simple but very effective analogy of indexing and querying can be done with books and words.

Let's say I remember I have a book in my library that has as main character someone called Ricardo and that tells about a story that is also based in Paris. Without any organization of my library I might need, in the worst case, to sequentially read all my books from start to finish to then find the one that I was looking for. This is not convenient at all, especially if I posses a lot of books. In case I maintained an index of in which book I can find any of the words from my whole library, I could quite rapidly find the few ones that contain a character

that get called Ricardito. Even more, if I had also an index that associates places with books that have scenes based in them, I could easily triangulate, without even needing to open a single book, that the one I was looking for is *Travesuras de la niña mala* of the Nobel Price Mario Vargas Llosa. This is an example of how, indexing sequencing data, *the words* and their metadata, *the places*, one can rapidly check which samples, *the books*, contain a requested value, without having to look at the raw data.

4.3.1 Representing sets of k -mer sets, state of the art

During my thesis I focused on k -mer based algorithms, i.e. that use strings of length k as basic unit, because of their proven scalability and mathematical simplicity. Their are also the main common theoretical and technical abstraction that is used by the research group. Here I will briefly introduce some of the most used data structures and algorithms to store collections k -mers and, in some cases, their counts. The process to index a dataset using k -mers is to represent it as a set of the k -mers that from their sequences, like remembering the set of unique words inside one or multiple books. This representation has to be searchable so then I can interrogate it for the presence of a particular word. There are three aspects to keep in count when considering such data structures: the computational complexity of building and, most of all, querying; the size of the data structure that stores the information and the kind of interrogations you can do with the data: presence/absence or metadata (like, for example, counts). This leads to the distinction between exact and approximate indexes and by the ones that support membership or metadata queries.

The membership query $memb(x)$ returns k -mers and other basic computational aspects that are at the basic of such data structure have been covered in the introduction.

4.3.2 Minimum set of operations and characteristics of these data structures

Given a set of sequencing samples, the data structure must be able to add k -mers from each sample to itself with an $insert()$ operation.

It also has to be able to return the presence of the absence of an element inside it, using a binary $memb()$ operation (0 for no, 1 for yes). The result of the $memb()$ operation can be exact or approximate, i.e. have false positives. If the data structure contains the number of times a k -mer has been seen in the input sample, the $memb()$ operation will return 0 if it has never been seen, and a value ≥ 1 if the value has been seen 1 or multiple times. The count can be exact or represent an order of magnitude of the counts: this is often needed to not saturate the counts as most datasets have skewed k -mer count distribution.

The data structure conserves actively or not its internal state after a membership query. For example when looking in a dictionary if an element is present, the CPU will have inside a chunk of memory containing the queried key-value pair and other ones. Other data structures store explicit variables to remember in

which place of their internal representation the *memb()* operation led to. This is important to notice as most of the times, sequences and not k -mers are queried to the data structure, meaning that *memb()* operations are done sequentially and on k -mers overlapping with each other. Leveraging these properties makes huge differences in the scalability of such data structures.

4.3.3 Simple data structures: sorted list and hash table

Indexing small sets of k -mers is in trivial. There are two well known data structures that can serve this goal. The most simple data structure used in computer science to maintain an ordered collection of elements to be searched in less than linear time is a sorted list of elements. By ordering the whole enumeration of the set of k -mers in each sample, one can use a binary search to find a requested k -mer in time $O(k \log n)$, using $O(kn)$ space. This is feasible for very basic cases with small set of k -mers but it is intractable for the aforementioned use-cases, as both time to query a single element or store the dataset scale too poorly.

Hash-tables, a well known implementation of dictionaries (or maps) in computer science, solve the problem of the query time, bringing it to $O(k)$ or $O(1)$, depending on the particular hash function used. They still require $O(kn)$ space that makes them still unusable for large collections of data.

4.3.4 Approximate membership and filters

Approximate membership data structure offer a trade-off between the space (in memory or disk) used to store the ingested information and probability of returning a correct answer. While a sorted list or a hash table return always the correct answer to a , these data structures answer with a non-zero probability of false-positive (i.e. reporting a k -mer present in the raw data when in fact it is not) and zero false-negative rates (i.e. reporting a k -mer as not present while it was present).

4.3.4.1 Bloom Filters

4.3.4.2 Quotient Filters

4.4 Converting ccdBGs into unitig matrices for downstream analyses: Muset

Matrix: every genome can be seen as a binary vector in a matrix across the alleles of the graph. This way you can use all known downstream applications on matrices: statistics and population genetics can be generalized to this model.
